"Low-Dimensional Transport and Large Thermoelectric Power Factors in Bulk Semiconductors by Band Engineering of Highly Directional Electronic States"

Bilc, Daniel I. ; Hautier, Geoffroy ; Waroquiers, David ; Rignanese, Gian-Marco ; Ghosez, Philippe

ABSTRACT

Thermoelectrics are promising for addressing energy issues but their exploitation is still hampered by low efficiencies. So far, much improvement has been achieved by reducing the thermal conductivity but less by maximizing the power factor. The latter imposes apparently conflicting requirements on the band structure: a narrow energy distribution and a low effective mass. Quantum confinement in nanostructures and the introduction of resonant states were suggested as possible solutions to this paradox, but with limited success. Here, we propose an original approach to fulfill both requirements in bulk semiconductors. It exploits the highly directional character of some orbitals to engineer the band structure and produce a type of low-dimensional transport similar to that targeted in nanostructures, while retaining isotropic properties. Using first-principle calculations, the theoretical concept is demonstrated in Fe2YZ Heusler compounds, yielding power factors 4 to 5 times larger than in classical thermoelectrics at room temperature. Our findings are totally generic and rationalize the search of alternative compounds with similar behavior. Beyond thermoelectricity, these might be relevant also in the context of electronic, superconducting, or photovoltaic applications.

(Received 4 September 2014; published 31 March 2015)

Thermoelectrics are promising for addressing energy issues but their exploitation is still hampered by low efficiencies. So far, much improvement has been achieved by reducing the thermal conductivity but less by maximizing the power factor. The latter imposes apparently conflicting requirements on the band structure: a narrow energy distribution and a low effective mass. Quantum confinement in nanostructures and the introduction of resonant states were suggested as possible solutions to this paradox, but with limited success. Here, we propose an original approach to fulfill both requirements in bulk semiconductors. It exploits the highly directional character of some orbitals to engineer the band structure and produce a type of low-dimensional transport similar to that targeted in nanostructures, while retaining isotropic properties. Using first-principle calculations, the theoretical concept is demonstrated in Fe₂YZ Heusler compounds, yielding power factors 4 to 5 times larger than in classical thermoelectrics at room temperature. Our findings are totally generic and rationalize the search of alternative compounds with similar behavior. Beyond thermoelectricity, these might be relevant also in the context of electronic, superconducting, or photovoltaic applications.

Thermoelectricity, realizing the direct conversion between thermal and electrical energies, is a very promising avenue for renewable energy generation. The efficiency of a thermoelectric (TE) material can be described by its figure of merit \(ZT\), defined as \(ZT = (S^2\sigma T)/(\kappa_e + \kappa_l)\), where \(S\) is the thermopower, \(\sigma\) the electrical conductivity, \(T\) the absolute temperature, and \(\kappa_e\) and \(\kappa_l\) the electronic and lattice contributions to the thermal conductivity. In practice, \(ZT\) should be greater than 3 for TE devices to become fully competitive with other energy conversion systems [1,2]. Unfortunately, more than fifty years after the promising discovery of Bi₂Te₃-based alloys with \(ZT \sim 1\) [3], increasing \(ZT\) further remains a real challenge. Huge efforts have been dedicated to the lowering of \(\kappa_l\) using specific crystal structures (e.g., phonon glass-electron crystals [4]) and nanostructuring [5–9], leading to the generation of materials with \(ZT = 1–2.4\) within the last decade [10–12]. Record low values of \(\kappa_l = 0.22 – 0.5\) W/mK [8,10] were achieved, and it is unlikely that these values can still be significantly decreased. At this stage, as emphasized by Kanatzidis [8], the next step forward should come from new breakthrough ideas on how to significantly enhance \(S^2\sigma\), the power factor (PF).

A promising avenue was proposed by Hicks and Dresselhaus [5,13], who predicted theoretically that quantum confinement of electrons in multiple wells can substantially increase the PF. It was confirmed experimentally that the PF in the confined region of nanostructures [14,15] can indeed be larger than in related bulk materials. However, the gain in the confined region is partly counterbalanced by the contribution from the barrier material producing the confinement. More recently, Mahan and Sofo [16] searched for what should be the ideal shape of the so-called transport distribution function that optimizes \(ZT\). They reached the conclusion that the best materials would combine (i) a distribution of carrier energy as narrow as possible and (ii) high carrier velocities in the direction of the applied field. Satisfying both of these criteria seems difficult in practice: narrow energy distributions are typically associated with flat energy bands, while high carrier velocities are necessarily associated with highly dispersive bands. This could be partly achieved in rare-earth compounds like YbAl₃, yielding very large PF at low temperatures [17]. However, those are metals with TE properties rapidly decreasing with increasing \(T\). Alternatively, attempts to combine these apparently incompatible requirements in semiconductors have relied on the “band structure engineering” of narrow energy features in the density of states from in-gap and resonant states near the band edges [18–22].

Here, we show theoretically that the seemingly conflicting requirements formulated by Mahan and Sofo [16] can actually be combined within the same band of certain semiconductors, exploiting the highly directional character of some orbitals. This is achieved without any nanostructuring or introduction of resonant states. It yields, in the bulk phase, a type of low-dimensional transport similar to that targeted by Hicks and Dresselhaus in nanostructures [5], while simultaneously retaining isotropic transport properties.
at the macroscopic level, concretizing ideas recently proposed by Parker et al. [23]. The concrete consequences of this finding on the TE properties is demonstrated in the class of Fe$_2$YZ full Heusler compounds: by engineering the appearance of Fe $e_g$ states at the bottom of the conduction bands, power factors 4 to 5 times larger than in classical thermoelectrics (such as PbTe or Bi$_2$Te$_3$) can be obtained at room temperature. Beyond revealing the unexpected interest of a class of compounds often considered as modest thermoelectrics [24], our results rationalize the search of alternative compounds with an optimal power factor. The underlying concepts are totally generic and can be combined with other known strategies for decreasing the thermal conductivity in order to increase the TE figure of merit.

The electronic properties were studied within density functional theory using CRYSTAL [25]. We adopted a B1-WC hybrid functional scheme [26] which was previously shown to be accurate for describing the electronic and TE properties of this class of compounds [21]. The electronic transport properties were studied within the Boltzmann transport formalism and constant relaxation time approximation implemented in BoltzTraP [27]. Within this approximation, $S$ is independent of the relaxation time $\tau$, whereas $\sigma$ and PF depend linearly on $\tau$. The relaxation time was set to $\tau = 3.4 \times 10^{-14}$ s in all of the calculations. This value was determined by fitting the electrical resistivity $\rho$ to the experimental value of 0.65 m$\Omega$ cm for Fe$_2$VAl$_{1-x}$M$_x$ ($M = $ Si, Ge) systems at doping $x = 0.03$ and 300 K [24,28]. For Fe$_2$VAl, the calculated PF is 3 mW/mK$^2$ (Fig. 1), in close agreement with experimental data. In order to estimate with more accuracy $ZT$ at high $T$, we went beyond constant relaxation time approximation and considered $T$ and energy $E$ dependences of the relaxation time $\tau(T, E)$ for the acoustic and polar optical phonon scattering mechanisms (Ref. [29], text). The thermodynamical stability was assessed using the generalized gradient approximation from Perdew, Burke and Ernzerhof within a plane augmented wave approach and using VASP [53,54].

The computational parameters and pseudopotentials are similar to the ones used in the Materials Project [55,56]. For each chemical system (e.g., Fe-Ti-Sn), we computed the chemistry in the Heusler crystal structure but also other ternary crystal structures obtained from Heusler-forming systems. The stability of each Heusler phase was evaluated versus all phases present in the Materials Project and our generated ternary phases using the convex hull construction implemented in the pymatgen package [57].

We start our search from Fe$_2$VAl, which, in spite of relatively modest TE properties ($ZT \sim 0.13 - 0.2$ [24,58], PF = 4–6 mW/mK$^2$ [24,28] at 300–400 K), is considered for low-cost TE applications [59]. As clarified recently [21], it is an intrinsic semiconductor, with a low band gap between the highest valence bands of dominant Fe $t_{2g}$ character and a highly dispersive lowest conduction band of dominant V $e_g$ character (see the dotted line in Fig. 1). Interestingly Fe$_2$VAl also exhibits a “flat-and-dispersive” band of Fe $e_g$ character that is very flat along the $\Gamma X$ direction of the Brillouin zone and highly dispersive along others (see the bold line in Fig. 1). This band combines the above-mentioned features identified by Mahan and Sofo to produce a large PF. It lies, however, $\sim$0.6 eV above the bottom of the conduction band and is not active in transport at room temperature for optimal doping at electron concentrations $n \sim 10^{19}$ cm$^{-3}$. In order to move its position towards the bottom of the conduction band, we performed atomic substitutions at the Y and Z sites.

We consider in Fig. 1 a first set (S1) of Fe$_2$YZ full Heusler compounds with $Y = $ V, Nb, Ta and $Z = $ Al, Ga, In. Going from 3d to 5d transition metal elements at the Y site tends to move the $Y e_g$ dispersive band upwards. Furthermore, going to higher-mass elements at the Y and Z sites increases the lattice parameter (and the Fe-Fe distance), resulting in a decrease of Fe-Fe interactions lowering the Fe $e_g$ levels (Ref. [29], text). Consequently, in many compounds, the Fe $e_g$ flat-and-dispersive band appears close to the bottom of the conduction band. In line
with our expectations, this increases the PFs at 300 K from ~3 mW/mK² for Fe₂VAl to ~12 mW/mK² for Fe₂NbAl and Fe₂TaAl, and up to 16–20 mW/mK² for Fe₂NbGa, Fe₂TaGa, Fe₂NbIn, and Fe₂TaIn (Fig. 1 and Ref. [29], Fig. 4). Band-by-band analysis for Fe₂TaIn shows that most of the PF (90%) comes from the Fe e₉ bands. These compounds also exhibit extremely large PFs of ~14–17 mW/mK² at 300 K, consistent with what was reported in Ref. [60]. This time, the large PF is almost entirely generated by the Fe e₉ flat-and-dispersive band (~93% of the total PF for Fe₂TiSn (Ref. [29], Fig. 6).

In a second set (S2) of Fe₂YZ compounds with Y = Ti, Zr, Hf and Z = Si, Ge, Sn, the dispersive Y e₉ band is pushed up even higher in energy. It appears well above the Fe e₉ bands, which are now the only lowest conduction bands (Fig. 1 and Ref. [29], Fig. 5). These compounds also exhibit extremely large PFs of ~14–17 mW/mK² at 300 K, consistent with what was reported in Ref. [60]. This time, the large PF is almost entirely generated by the Fe e₉ flat-and-dispersive band (~93% of the total PF for Fe₂TiSn (Ref. [29], Fig. 6)).

In all S1 and S2 compounds exhibiting enhanced TE properties, the PF remains substantial (i.e., keeps 90% of its peak value) in a similar and relatively wide range of carrier concentrations (n ≈ 4 × 10²⁰ to 3 × 10²¹ cm⁻³), at which |S| ~ 150–200 μV/K. These compounds then exhibit large S, comparable to those of Fe₂VAl and the best classical thermoelectrics, but at n and σ values that are about one order of magnitude larger (Ref. [29], Fig. 7).

Taking Fe₂TiSn as a representative example, the inspection of the carriers contributing to the transport properties at 300 K provides further insight into the enhancement of the PFs with respect to Fe₂VAl [Figs. 2(c) and 2(d)]. In the latter, the sizable TE properties at optimal doping arise from electrons located in small pockets centered at X and associated with highly dispersive V e₉ bands [Fig. 2(c)]. In Fe₂TiSn, the enhanced transport properties at optimal doping are produced instead by electrons from the Fe e₉ lowest conduction states located in three orthogonal tubes extending along Γ-X directions and intersecting at Γ [Fig. 2(d)]. These tubes can be viewed as the juxtaposition along the entire Γ-X direction of consecutive electron pockets similar to those of Fe₂VAl, thereby explaining the improved transport properties. This is an optimal realization of the concept of pocket engineering brought forward by Snyder et al. [61] where large S and σ values are obtained without compromising mobility by introducing degenerate low effective mass pockets in the Brillouin zone.

In each Cartesian direction, the Heusler Fe₂YZ structure can be seen as made of Fe₂ (alternating with YZ) atomic planes. For clarity, only the family of {001}-Fe₂ planes is illustrated in Fig. 2(a), but similar families can be drawn along the two other Cartesian directions. The tubular shape of the Fermi surface of Fe₂TiSn and related compounds is originating from the highly directional character of the Fe e₉ orbitals. The conduction states of the three tubes in Fig. 2(d) are associated with the flat band along ΓX (and the symmetrically equivalent ΓY and ΓZ directions) in Fig. 1. For the tube along z, these states are made of Fe dₓ²−ᵧ²−z² orbitals (see Ref. [29], Fig. 3) which strongly overlap in {001}-Fe₂ planes [strong σ* bonds along x and y, Fig. 2(b)] but do not interact significantly from plane to plane (weak δ* bonds along z). The same is true, mutatis mutandis, for the tubes along x and y. This anisotropy of the orbital interactions gives rise to electronic bands that are highly
The results are summarized in Fig. 2(e). Stable and unstable thermodynamical stability of the S1 and S2 compounds. This was investigated at the first-principle level (Ref. [29]), similarly contributing to transport in a given direction: for instance, only the states in the tubes along x and y (the {100}- and {010}-Fe2 planes) contribute significantly to the transport along z. All of this is a concrete illustration that low-dimensional electronic structures can occur in high-symmetry cubic systems, as also proposed recently by Parker et al. [23] for another class of compounds.

From the practical point of view, a central issue concerns the thermodynamical stability of the S1 and S2 compounds. This was investigated at the first-principle level (Ref. [29], text). The results are summarized in Fig. 2(e). Stable and unstable phases are associated with green and red colors, respectively. Compounds previously synthesized are stable. Fe2TiGe and Fe2NbGa with good TE performance are predicted to be fully stable. We see that including elements like In, Zr, or Hf with large ionic radii tends to destabilize the Heusler structure, although the synthesis of Fe2HfSn might stay experimentally accessible. Another practical issue concerns the appearance of antisite defects in these Heusler compounds, which are detrimental to the TE performance [21]. From our calculations in Ref. [29], Table 2, S2 compounds appear to be less prone to form antisite defects than Fe2VAI.

The existence of several isostructural stable compounds with very attractive PF is an advantage for TE applications. Combining such compounds in solid solutions should allow for the reduction of κl [9] while preserving the shape of their electronic band structure at the conduction band bottom (nearly identical since dominated by the same Fe eg states, see Ref. [29], Fig. 5) and the related large PF. Such a reduction of κl has been demonstrated in Fe2V1−xWxAl alloys [58], reaching values of ~3 W/mK. The presence of heavier elements than V and Al is likely to lower κl of the new Heusler candidates compared to Fe2VAI. In this context, reasonably low values can be expected, for instance, in Fe2TiSn and its solid solutions (e.g., Fe2TiSn1−xS lx). With κl = 3.5 W/mK, we estimate ZT values larger than 1 for Fe2TiSn in the temperature range between 600–900 K (Ref. [29], Fig. 10). Such large ZT values are achieved at carrier concentrations only slightly lower than those corresponding to the optimum PF and at which S and n remain large. These ZT values are significantly larger than those predicted for Fe2VAI, which properly reproduce the experiment (ZT = 0.2 at 400 K with κl = 3.3 W/mK, in agreement with Ref. [58]). This attests that the beneficial effect on the PF, achieved through the low-dimensional transport in Fe2TiSn, can be accompanied by a significant increase of ZT without being systematically counterbalanced by another detrimental effect.

The excellent TE properties of some of the Fe2YZ compounds demonstrated theoretically in this Letter, combined with the low-cost and wide availability of their constituent elements, make them very attractive for large-scale TE applications, well beyond what could have been anticipated from previous studies of Fe2VAI. Going further, our results also highlight that, contrary to current beliefs, extremely large PF can be intrinsic to bulk semiconductors. Our work rationalizes how this can be achieved in practice through the engineering of highly directional states at the bottom of the conduction bands, yielding low-dimensional transport. This calls for a search for alternative families of compounds realizing the same ideas. The link that we establish with some basic requirements on the electronic band structure is particularly relevant to succeed identifying such compounds in the current context of emergent high-throughput searches for alternative thermoelectrics [63,64] that require clear and simple design rules. Our findings might also attract interest well beyond the field of thermoelectrics: the singular Fermi surface in these systems presents close similarities to those of Fe-based superconductors [65] and the associated low-dimensional transport might be relevant in the context of some electronic [66] or photovoltaic [67] applications.

[25] The 1D shape of a Fermi surface is associated with 2D transport in real space. Because of the orientation of the Fe-Fe bonds, the direction of the d_{x^2-y^2} orbitals, the latter can be viewed as the combination of two orthogonal transport channels along the Fe-Fe bonds.
