Abstract
Objectives: Accurate measurement of IgG subclass (IgGsc) levels are essential to aid in the diagnosis of disease states such as primary immunodeficiencies. However, there is no single standardisation of nephelometric and turbidimetric assays for these analytes and two reference materials have been utilised. We expand on previous reports and present data from a multi-site analysis that both identifies and quantitatively defines the differences in calibration resulting from the use of different reference materials. Design and methods: IgGsc antibodies in the serum specimens and reference materials were measured according to the manufacturers' instructions using commercially available IgGsc assays or components. Results: Data from four independent sites showed that in spite of the different commercial suppliers of IgGsc assays calibrating to different reference materials, ERM-DA470k and WHO67 /97, the resulting calibrations were comparable for IgG1 and IgG2. However, for IgG3 and IgG4 ...

Abstract

Objectives: Accurate measurement of IgG subclass (IgGSc) levels is essential to aid in the diagnosis of disease states such as primary immunodeficiencies. However, there is no single standardisation of nephelometric and turbidimetric assays for these analytes and two reference materials have been utilised. We expand on previous reports and present data from a multi-site analysis that both identifies and quantitatively defines the differences in calibration resulting from the use of different reference materials.

Design and methods: IgGSc antibodies in the serum specimens and reference materials were measured according to the manufacturers’ instructions using commercially available IgGSc assays or components.

Results: Data from four independent sites showed that in spite of the different commercial suppliers of IgGSc assays calibrating to different reference materials, ERM-DA470k and WHO67/97, the resulting calibrations were comparable for IgG1 and IgG2. However, for IgG3 and IgG4 the calibrations were significantly different. The use of assay specific normal ranges should compensate for these calibration differences, however, the two manufacturers’ assays can give differing clinical classifications. The agreement between the different manufacturers’ IgGSc assays was between 85.1% and 95.8% for all IgGSc assays, the discordance of sample classification for IgG1 and IgG2 assays was approximately 12% and 15% respectively, whilst that for IgG3 and IgG4 was 4% and 13% respectively.

Conclusion: We discuss the similarities and differences between assays that utilise the different reference materials.

Introduction

The measurement of IgG subclasses (IgGSc) is performed as part of an immune system evaluation where there is a continued clinical suspicion of an IgGSc imbalance, particularly in the background of normal total IgG levels. Deficiency in IgGSc levels has been found to be associated with a variety of immunodeficiency syndromes such as common variable immunodeficiency, ataxia telangiectasia and IgA deficiency as well as upper respiratory tract infections such as severe swine flu [1–6]. The measurement of all four IgGSc forms part of the accepted protocol for diagnosis of an IgG subclass deficiency. The concentration of IgGSc is age dependent and normal IgGSc concentrations change significantly as the immune system matures. In neonates, placental transfer plays an important part in determining IgGSc levels and the majority of IgG present at birth is derived from placental transfer from the mother. During the first 6 months of life levels decrease as the neonate develops the synthetic mechanisms to produce their own IgG. IgG1 and IgG3 levels increase most rapidly with near adult levels reached by the age of 12, adult levels of IgG2 and IgG4 are reached much more slowly. These significant differences between the IgGSc concentrations in children and adults have to be taken into account when interpreting IgGSc results. Both paediatric and adult normal ranges have been established for the IgGSc from the different commercial reagent suppliers to enable their use in disease diagnosis [7,8].

The standardisation of normal ranges for the measurement of IgGSc has proven difficult for several reasons: (1) different methods have been used for measurement, (2) study cohorts that have been used may differ in age, race, sex and number of subjects and (3) the use of different statistical analyses for data interpretation. Standardisation has been further hampered due to their being no single international reference material recognised for the determination for IgGSc. The three commercial sources of IgGSc assays use two different calibrations: in the case of The Binding Site (TBS) Certified Reference Material 470

Table 1
Intra-assay precision and sample linearity of TBS and Siemens IgGSc assays.
For intra-assay precision: twenty seven replicates were assayed for each sample in each of
the manufacturer's individual IgGSc assays and percent coefficient of variation (%CV) was
calculated.
For linearity: the samples were diluted to 75%, 50% and 25% of its original concentration
and the values of the dilution recorded. The percentage deviation from the expected
value was determined as described in materials and methods. All individual dilutions
were assayed in triplicate.

![Fig. 1. Box and Whisker plot showing the comparison between IgG subclass assays and different manufacturers. There is a good agreement between the IgG1 and IgG2 assays. For IgG3 and IgG4 a significant difference between the manufacturers’ assays is observed. The assays were run as described in the manufacturer’s inserts and the methods and materials section. The line in the middle of the box represents the median value of the combined data set from all study sites, the upper edge of the box represents the value of the upper quartile, the lower edge the value of the lower quartile. The high error bar represents the highest value and the low error bar the lowest value in the sample population.](1752)

**Materials and methods**

**Assay method**

IgGSc antibodies in the serum specimens and reference materials were measured according to the manufacturers’ instructions using commercially available IgGSc assays: SPAPLUS IgGSc assays (IgG1–IgG4; NK006.S, NK007.S, LK008.S, LK009.S; The Binding Site, UK). Siemens BNII IgGSc assays were performed with the following components: N AS IgG1 (OQXI092), N AS IgG2 (OQXK092), N Latex IgG3 (OPAV032), and N Latex IgG4 (OPAU032), N-supplementary reagent (QQTDD115), Siemens Cleaner SCS (QQUB195), and the N protein standard SL (OQIM135) (Siemens Healthcare Diagnostic Products, Germany).

The adult normal ranges stated for the TBS assays are IgG1: 3.82–9.29 g/L, IgG2: 2.42–7.00 g/L, IgG3: 0.22–1.76 g/L, IgG4: 0.04–0.87 g/L and for the Siemens assays IgG1: 4.1–10.1 g/L, IgG2: 1.7–7.9 g/L, IgG3: 0.11–0.85 g/L, IgG4: 0.03–2.0 g/L.

**Precision**

The precision of each assay was compared by running twenty seven replicates of the same sample on each assay on both manufacturers’ assays. The sample consisted of pooled human serum with IgGSc levels within the standard measuring range for each assay on both manufacturers’ assays.

**Linearity**

A serum sample was identified that gave a readable concentration towards the upper value of the measuring range for each IgGSc on both manufacturer’s assays. Dilutions of the samples were prepared at 75%, 50% and 25% concentration of the original fluid. The linearity of the IgGSc assays was assessed by running each dilution in triplicate and comparing the mean result to the expected results.

![IgG subclasses](1752)

![Manufacturer’s of IgG subclass assays](1752)
expected concentrations were calculated as a percentage of the concentration obtained at 100% (no dilution). The % deviation from linearity was calculated as \((\text{concentration obtained/concentration expected})*100\).

**Method comparison**

Randomly selected human serum samples were collected at each of the four independent sites and measured on each of the manufacturers' IgG subclass assays.

**Statistical analysis**

Pearson correlation, Altman–Bland analysis, and Deming regression analysis were all performed using Analyse-It software. Percent coefficient of variation was calculated in Excel using the following formula: ((Standard deviation/mean)*100).

| Table 2 | IgG subclass comparison characteristics between TBS and Siemens IgGSc assays. Human serum samples were assayed in four subclass assays from both manufacturers at four independent sites. **Results**

**Measurement of assay performance and sample comparison**

Intra-assay precision and sample linearity were calculated for each assay (Table 1) with one sample assayed per IgG subclass. The intra-assay precision for all IgG subclasses were ≤5% with IgG3 subclass assays the least precise for each manufacturer. The linearity study showed that deviation from the expected values were <10% for all assays with the exception of the sample diluted to 25% of its original concentration in the Siemens IgG1 assay which showed a variation of 16.6% from the expected value.

Results from the comparison studies using both manufacturers' assays are shown in Fig. 1 and Table 2. The correlation between the IgG1 and IgG2 values were good (Deming regression slope IgG1: 0.81–0.98 and IgG2: 0.98–1.13). Correlation of IgG3 and IgG4 however suggested significant differences existed between the values obtained on the different manufacturers' assays (Deming regression slope IgG3: 1.53–2.18 and IgG4: 0.50–0.63).

**Quantitation of assay comparison**

The values obtained for both the IgG1 and IgG2 in ERM-DA470k were within 15% of each other when assayed with either TBS IgGSc or Siemens IgGSc assays (Fig. 2). The difference between the values obtained for IgG3 and IgG4 with the different manufacturers' assays, however, was much greater and further supported the observation of substantial calibration differences between the two manufacturers' assays. For IgG3 the percentage difference in values obtained was ≈40% (304 mg/L in the Siemens assay vs. 559 mg/L in the TBS assay) and >60% in the IgG4 assay (907 mg/L in the Siemens assay vs. 374 mg/L in the TBS assay).

**Effect of different calibrations on sample classification**

We investigated whether there were any differences in sample classification due to the calibration differences between the TBS and Siemens IgGSc assays, particularly the IgG3 and IgG4, for a range of samples measured at the four sites (Table 3).

The overall agreement between the different IgGSc assays, that is the percentage of samples that fell into the same classification on both assays, was >85% in all four IgGSc assays (85.1%–95.8%). Even though the linear regression analysis of the results from the IgG1 and IgG2 assays gave slopes suggesting reasonable agreement and certainly far closer agreement than between the IgG3 and IgG4 assays, the discordance of sample classification for both the IgG1 and IgG2 assays was...
approximately 12% and 15% respectively, whilst that for IgG3 and IgG4 was 4% and 13% respectively (Table 3).

Discussion

The accurate and reproducible measurement of IgG subclasses is essential to aid the diagnosis of both hypo- and hyper-gammaglobulinaemias particularly in the presence of normal serum IgG levels. The concentration of IgG subclasses can vary with age, gender, race, laboratory to laboratory due to method differences as well as reference material and calibration differences. Bossuyt and colleagues previously noted that disparity exists between IgG subclass assay results at different laboratories. However, despite the differences in laboratory results, most laboratories agree that the concentration of IgG3 varies with age, gender, race, and laboratory. The concentration of IgG subclasses can also vary with age, gender, race, and laboratory.

In summary, we have provided detailed evidence that the calibration in the early reference material WHO 67/97 and its suitability for nephelometric or turbidimetric assays. Whicher reported the precipitation of residual proteins from long term storage of WHO material [16] which has been shown to decrease the precision of nephelometric and turbidimetric assays. Klein and colleagues reported that the levels of IgG3 were unstable in WHO 67/97 and may be the reason for the laboratory to laboratory variation observed in the measurement of WHO 67/97 IgG3 concentrations obtained and the under reading of IgG3 levels [10].

It appears likely that the lower calibration of IgG3 adopted in the Siemens assay may be due to the degradation of IgG3 in the early reference preparation WHO 67/97 and this view is further supported by the many publications that have investigated the levels of the IgG subclasses (Table 4). With the exception of one study the results clearly indicate with considerable consistency that the concentration of IgG3 > IgG4 in human serum. The relative concentrations of IgG subclasses in CRM470 have been determined nephelometrically to be IgG1 > IgG2 > IgG3 > IgG4 [7] and are in agreement with published literature in Table 4. CRM470 (replaced by ERM-DA470k due to stock exhaustion) was accepted as the International Reference Preparation for proteins in human serum in 1992 and the long term stability of the analytes including IgG has been shown.

However, although the IgG1 and IgG2 assays have similar calibrations and give comparable values on patient samples, the normal ranges within the manufacturers’ inserts differ significantly. When these are applied this leads to classification discordance of up to 15% between the patient samples assessed in this study and thus emphasises the requirement to use manufacture specific normal ranges and the lack of assay interchangeability.

Standardisation of immunoassays is necessary to minimise inter-laboratory variation and the implementation of CRM 470 for the major serum assays illustrates how this approach can be successful. A common reference material is required for standardisation and therefore ideally, a single internationally accepted reference material should be adopted for the IgG subclass assays; in the absence of this an appropriate conversion factor between the different materials may be beneficial. However, manufacturer normal ranges are supplied with each assay which should in theory compensate for the impact of using different reference materials for their respective calibration. This was indeed the case for IgG3 and IgG4 in this study but there were surprisingly large differences between sample classifications when measuring IgG1 and IgG2, harmonisation of reference ranges would also be required to minimise inter-laboratory differences.

In summary we have provided detailed evidence that the calibration of IgG1 and IgG2 Siemens and Binding Site assays are similar but that the calibration of IgG3 and IgG4 assays are significantly different and we have provided a plausible explanation for this difference. For all IgG subclasses the assay ranges quoted in the manufacturers’ inserts

### Table 3

Sample classification in the TBS and Siemens IgG subclass assays.

Randomly selected human serum samples were run at four independent locations (IgG1, n = 121; IgG2, n = 167; IgG3, n = 141; IgG4, n = 121) on all four IgG subclass assays. The resulting sample values were classified using the normal ranges in each manufacturer’s assay. (1) low, below the stated normal range; (2) normal, within the stated normal range and (3) high, higher than the stated normal range.
