Abstract

Starvation for a single essential amino acid induced differentiation of the human promyelocytic leukemia line HL-60 into morphologically and functionally mature granulocytes. Differentiation occurred when protein synthesis was inhibited up to 90% but was not simply secondary to growth arrest or protein synthesis inhibition, because neither glucose starvation nor treatment with protein synthesis inhibitors induced differentiation. Induction of differentiation by an aminocyl tRNA synthetase inhibitor and the effect of cycloheximide and puromycin on amino acid-starved cells suggested an important regulatory role of tRNA molecules during differentiation.

Introduction

During cellular differentiation, quantitative and qualitative changes in gene expression occur. The underlying regulatory mechanisms are poorly understood but operate at the transcriptional, translational and posttranslational levels (1, 2). A better understanding of these regulatory mechanisms could lead to new forms of therapy of acute human leukemias where the cells are arrested at different stages of maturation (3). The human promyelocytic leukemia cell line HL-60 is an established model for studying hematopoietic cell differentiation in vitro (4, 5). These immature cells can be induced by various compounds to differentiate along either the granulocytic or monocytic lineage into functionally and morphologically mature nonproliferating cells (4, 5).

We found that starvation for a single essential amino acid induced granulocytic differentiation of HL-60 cells. Changes in tRNA molecules appeared to play an important regulatory role in the differentiation process because (a) the degree of differentiation correlated with the degree of amino acid starvation (tRNA aminoacylation varies with amino acid availability), (b) histidinol, an aminocyl tRNA synthetase inhibitor, induced differentiation, and (c) cycloheximide prevented differentiation in amino acid-starved cells whereas puromycin had a much weaker effect.

Methods

Origin of cell line and culture conditions. The human promyelocytic cell line HL-60 was obtained from Dr. Karen Willard-Gallo of the International Institute of Cellular and Molecular Pathology, Brussels, Belgium; she had previously obtained it from the American type culture collection, Rockville, MD. The cells were routinely grown in RPMI-1640 medium (Irvine Scientific Co., Irvine, CA) supplemented with 2 mM glutamine and 10% fetal bovine serum (FBS) (Irvine Scientific Co.); they were diluted biweekly to a density of 0.15 × 10^6 cells/ml.

Cells were recovered by centrifugation from the growth medium and resuspended at a density of 0.15 × 10^6 cells/ml in experimental medium consisting of RPMI-1640 medium lacking one amino acid or glucose that was supplemented with 2 mM glutamine, 5 ng/ml sodium selenite and 10% horse serum (Irvine Scientific Co.) that had been heat-inactivated at 56°C for 30 min and extensively dialyzed against 0.9% NaCl. The amino acid or glucose was added to the desired concentration. When this concentration was the same as in the formulation for RPMI-1640 medium, the medium was referred to as complete experimental medium. The cells were cultured in 6-well cluster dishes at 37°C in a 95% air/5% CO₂ humidified atmosphere. Cycloheximide, emetine, puromycin, or dimethyl sulfoxide (DMSO) was added to some of the cultures in complete experimental medium at time zero.

Measurement of HL-60 differentiation. Differentiation of HL-60 cells along the myelocytic series requires 4–7 d (4, 5). In fully differentiated HL-60 cells, as in normal granulocytes, membrane perturbation (e.g., by phorbol-12-myristate-13-acetate [PMA]) stimulates a number of biochemical reactions collectively referred to as the phagocytic "respiratory burst" (6). These reactions include superoxide anion production and increased glucose oxidation via the pentose phosphate pathway; they can be assessed by counting the number of nitroblue tetrazolium (NBT) reducing cells or by measuring 14CO₂ release from [1-14C]glucose, respectively (6). Unless otherwise noted, measurements of HL-60 differentiation were performed on day 6 of culture.

For the studies with NBT, which assesses functional maturity on an individual cell basis, 1 × 10^6 cells were incubated for 30 min at 37°C in 0.5 ml phosphate-buffered saline with 1 mg/ml NBT, 100 ng/ml PMA, and 20% dialyzed FBS. At least 200 cells were evaluated per culture and only cells containing at least three blue-black precipitates were counted as positive.

For the measurement of [1-14C]glucose oxidation, which quantitatively measures functional maturation of the cell population, 5 × 10^6 cells were recovered by centrifugation from each of the duplicate cultures. They were resuspended at a density of 1.5 × 10^6 cells/ml in glucose-free, Hepes-buffered RPMI-1640 medium supplemented with 2 mM glutamine and 2 mg/ml dialyzed bovine serum albumin. Two 1-ml aliquots of this cell suspension were transferred to 16 × 100-mm glass tubes, and PMA was added to one aliquot at a final concentration of 50 ng/ml. After 5 min at 37°C in a shaking water bath, 0.4 µCi of [1-14C]glucose (final
concentration 1 mM; Amersham Corp., Arlington Heights, IL) was added, and the reaction was terminated 20 min later by adding perchloric acid.

\[ ^{14}\text{C} \text{O}_2 \] was collected and counted as previously described (7). The assay was linear to 30 min and at cell densities between 0.5 to 2.5 \( \times 10^6 \) cells/ml. The data are expressed as nmol of \( ^{14}\text{C} \text{O}_2 \) released per 30 min per \( 10^6 \) cells. PMA-stimulated [\( ^{1-14}\text{C} \)]glucose oxidation was the difference in values between the presence and absence of PMA.

Morphological maturation was determined by Wright's stain; at least 200 cells were counted and slides were reviewed in a blinded fashion by a hematologist. The percent of cells that had differentiated into metamyelocytes and granulocytes correlated approximately with the percent NBT positive cells.

Measurement of cell growth and protein synthesis. Cell increment was calculated from the cell density at day 0 and day 4 measured by Coulter counter (Coulter Electronics, Hialeah, FL); the control cultures grew exponentially during this time. When control cultures were fed on day 3 by a 1:5 dilution with fresh medium, exponential growth continued until day 6; cell viability and the degree of spontaneous differentiation on day 6 were similar in the nonfed and fed control cultures. Cell viability was determined by trypan blue exclusion and exceeded 85% in all cultures. Protein synthesis was measured after 48 h of culture by 1 h of [\( ^3\text{H} \)]leucine incorporation into acid-precipitable material as described previously (8). Protein synthesis in amino acid-deficient or glucose-deficient cultures decreased until this time, remaining relatively constant thereafter. In preliminary experiments we found no difference in [\( ^3\text{H} \)]leucine incorporation when control cells were incubated in their original medium or fresh medium, thus indicating little change in the leucine concentration over the first 48 h of culture.

Results

HL-60 differentiation during amino acid starvation. When HL-60 cells were cultured in experimental medium that contained a growth-limiting concentration, 3–10 \( \mu \text{M} \), of an essential amino acid, a large proportion of the cells differentiated into morphologically and functionally mature metamyelocytes and granulocytes after 6 d (Fig. 1). Similar results were obtained at 3 \( \mu \text{M} \) of these three amino acids or with 10 \( \mu \text{M} \) of arginine, isoleucine or lysine. The concentration of these latter three amino acids in complete medium is 1.15 mM, 380 \( \mu \text{M} \), and 274 \( \mu \text{M} \), respectively. Differentiation was not observed when a nonessential amino acid, e.g., proline or serine, was either omitted from the medium or present at 10 \( \mu \text{M} \). When the effect of starvation for different essential amino acids was compared, there was a noticeable correlation between the degree of growth and protein synthesis inhibition and the degree of differentiation (Fig. 1). The degree of differentiation during valine starvation was similar to that obtained with 1% DMSO, an established and very effective inducer of HL-60 differentiation (5). Cycloheximide, puromycin, or emetine, at concentrations that inhibited growth and protein synthesis to similar degrees as did amino acid starvation, did not induce differentiation (Fig. 1). Moreover, when cells were incubated in growth-limiting glucose concentrations, 10–500 \( \mu \text{M} \), growth and protein synthesis were inhibited similarly as for cells in amino acid-deficient medium, but differentiation was not observed (results with 100 \( \mu \text{M} \) glucose are shown in Fig. 1). Thus, differentiation during amino acid starvation was not simply secondary to growth or protein synthesis inhibition but appeared related to some factor unique to amino acid starvation that correlated with the degree of starvation.

Time course of HL-60 differentiation during amino acid starvation. A significant increase in PMA-stimulated [\( ^{1-14}\text{C} \)]glucose oxidation was detected as early as 48 h after initiation of cultures in either tyrosine-free medium or in medium containing 3 \( \mu \text{M} \) tyrosine (Fig. 2, open squares and circles, solid lines). At this time, tyrosine had to be added to the tyrosine-free cultures to prevent cell death; \( \sim 50–60\% \) of cells in these tyrosine-added cultures were NBT reducing at days 5–6 when PMA-stimulated [\( ^{1-14}\text{C} \)]glucose oxidation was maximal (Fig. 2, closed squares, dotted lines). In cells cultured in medium containing 10 \( \mu \text{M} \) tyrosine (open triangles, solid lines), maturation lagged \( \sim 1 \text{d} \) behind that of cultures in 3 \( \mu \text{M} \) tyrosine (open circles, solid lines), but by day 7 both were as morphologically and functionally mature as cells cultured in 1–1.2% DMSO.

Commitment to terminal differentiation occurred during amino acid starvation with the time to commitment dependent on the initial amino acid concentration. In cells cultured in 3 \( \mu \text{M} \) tyrosine, commitment occurred between 48 and 72 h. Thus, when 50 \( \mu \text{M} \) tyrosine was added at 48 h, PMA-stimulated [\( ^{1-14}\text{C} \)]glucose oxidation was maximal on day 5 (Fig. 2, solid circles,

Figure 1. Effect of amino acid starvation, protein synthesis inhibitors, glucose starvation, and DMSO on HL-60 cells. Top, growth and protein synthesis; bottom, differentiation. Cultures were initiated at a density of 0.15 \( \times 10^6 \) cells/ml in either complete experimental medium containing 72 \( \mu \text{M} \) histidine, 110 \( \mu \text{M} \) tyrosine, 400 \( \mu \text{M} \) valine, and 10 mM glucose, or in otherwise complete medium containing either 10 \( \mu \text{M} \) histidine, 10 \( \mu \text{M} \) tyrosine, 10 \( \mu \text{M} \) valine, or 100 \( \mu \text{M} \) glucose. Cycloheximide (Cycl), emetine (Emet), puromycin (Puro), or DMSO was added at the indicated concentration at time zero to cultures in complete medium. Cell growth, protein synthesis, and functional maturation, as assessed by PMA-stimulated [\( ^{1-14}\text{C} \)]glucose oxidation and NBT reduction, were measured as described fully under Methods. All values are the mean±SD of at least three independent experiments performed in duplicate.
dotted lines) with only ~ 40-50% of the cells reducing NBT. The decrease in PMA-stimulated [1-14C]glucose oxidation after day 5 could be explained by the continued growth of the undifferentiated cells (data not shown). In contrast, addition of 50 μM tyrosine at 72 h did not inhibit differentiation (Fig. 2, closed circles, dashed lines). In cells cultured in 10 μM tyrosine commitment lagged ~ 1 d behind that of cells in 3 μM tyrosine. Thus, 50 μM tyrosine added at 48 h completely prevented differentiation (Fig. 2, closed triangles, dotted lines), but when added at 72 h a time course of PMA stimulation (Fig. 2, closed triangles, dashed lines) and NBT reduction was found that was similar to that observed in the 3 μM tyrosine cultures that had 50 μM tyrosine added at 48 h. These findings are in agreement with previous observations that the portion of cells that become committed to differentiation is dependent on inducer exposure time and concentration (9).

**HL-60 differentiation during histidinol treatment.** Histidinol is a specific histidine aminoacyl tRNA synthetase inhibitor and consequently causes nonaminoacylated (uncharged) tRNA^His to accumulate (10, 11). When 1 mM histidinol was added at day 0 to cells in complete experimental medium, which contains 72 μM histidine, PMA-stimulated [1-14C]glucose oxidation was 15.2±1.9 nmol/30 min/10^6 cells on day 6, and ~ 71±11% of the cells reduced NBT (values are mean±SD of three independent experiments performed in duplicate). This degree of differentiation was slightly greater than that found when cells were incubated in 10 μM histidine (Fig. 1) but approximated that found when cells were incubated in 3 μM histidine (data not shown). Induction of differentiation by histidinol was competitive with the medium histidine concentration with a ratio of ~ 12:1 generally yielding maximal differentiation.

**Effect of cycloheximide and puromycin on HL-60 differentiation during amino acid starvation.** Cycloheximide and puromycin inhibit protein synthesis by different mechanisms. Cycloheximide inhibits ribosomal peptidyl synthetase activity whereas puromycin allows peptide bond formation to proceed with release of incomplete peptides (12). In amino acid-starved cells cycloheximide increases the degree of tRNA aminoacylation whereas puromycin does not (13, 14). We found that cycloheximide added to cultures in medium containing 3 μM or 10 μM tyrosine completely prevented differentiation without affecting cell growth or viability whereas puromycin only partly prevented differentiation of these starved cells (Table I).

**Discussion**

It is remarkable that the numerous morphological and functional changes associated with differentiation can occur during amino acid starvation when protein synthesis is < 10% of control values (as measured at 48 h when cultures were initiated in 10 μM valine [Fig. 1] or 3 μM tyrosine [data not shown]). This suggests efficient regulation of gene expression. Amino acid starvation decreases rRNA and tRNA synthesis with little change initially in mRNA synthesis (10, 14, 15). In HeLa cells amino acid analogues, which partially mimic the effect of amino acid starvation, initiate a stress response with preferential translation of stress-related mRNAs and inhibition of translation of nonstress-related mRNAs.

Cultures were initiated in experimental medium containing 110 μM tyrosine (control), or 10 μM tyrosine in the presence or absence of protein synthesis inhibitors; after 6 d, the degree of differentiation was assessed as described under Methods. Cycloheximide had no additional inhibitory effect on cell growth in tyrosine-deficient media whereas puromycin decreased the final cell count by ~ 10%. Amount of protein synthesis inhibition was similar with both drugs.
mRNAs (16). Similar mRNA discrimination may be operative during amino acid starvation of HL-60 cells and this may be one of the mechanisms controlling gene expression during myeloid cell differentiation.

In addition to changes in RNA synthesis, a variety of other metabolic changes occur when mammalian cells are deprived of an essential amino acid. Most of these also occur during protein synthesis inhibitor treatment or glucose starvation (7, 8, 17). However, decreased aminooxylation of the cognate tRNA with uncharged tRNA accumulation is unique to amino acid starvation (11, 13) suggesting that uncharged tRNA molecules were involved in HL-60 differentiation during amino acid starvation. Two other pieces of evidence also suggest that uncharged tRNA molecules were important in the induction of HL-60 differentiation by amino acid starvation: first, the induction of differentiation by histidinol with the inverse correlation between the degree of differentiation and the medium histidine concentration, and second, the differential effect of cycloheximide and puromycin on differentiation during amino acid starvation.

Significant qualitative and quantitative changes in tRNA isospecies occur during differentiation of plant cotyledons, insect larvae, amphibian embryos, and mouse erythroleukemia cells, thus suggesting an important regulatory role of tRNA during cellular differentiation (18, 19). Amino acid starvation can cause unequal aminooxylation of the cognate tRNA isospecies (18), and because of tRNA hypomodification can cause changes in both cognate and noncognate tRNA isospecies (20). Changes in the intracellular availability of certain aminooxylated tRNA isospecies can lead to mRNA discrimination (21, 22). Amino acid starvation of HL-60 cells may allow further elucidation of the mechanisms involved in the regulation of gene expression during human myeloid differentiation and, in particular, the role of tRNA molecules.
