ABSTRACT

The study aims to determine the impact of Cd ($20~\mu M$) and Zn ($100~\mu M$) in the presence or absence of Si (2~m M) on plant development and fibre differentiation in young stem of hemp (*Cannabis sativa* L.). Gene expression and proteome involved in fibre development were analyzed. Both elements reduced the diameter of primary bast fibres. Cadmium negatively affected cellulose and lignin biosynthesis and decreased substitution of xylan in fibres, while Zn had an opposite impact on cellulose metabolism. Only a minor proportion of proteins were affected by both Cd and Zn, suggesting that the two heavy metals have a quite different impact on protein regulation in *C. sativa*. Si had a specific impact on some proteins observed in CdSi treatment comparatively to plants exposed to Cd in the absence of Si: 55 % of those proteins (10 among 18) were specifically regulated by this treatment and remained unaffected by Cd or Si applied alone. Six proteins were significantly regulated in ZnSi-exposed plants comparatively to Zn-treated ones and none of them was specifically regulated by Si in the absence of Zn. Diameter of bast fibre increased in response to Si in Cd-treated plants. This confirms that the presence of protecting Si confers a specific physiological status in relation to cell wall differentiation to heavy metal-treated plants.

1. Introduction

Human activities related to urbanization, industrialization and agriculture practices have resulted in the accumulation of heavy metals in soils and water in numerous areas of the world. Management of these contaminated sites constitutes a major environmental challenge since heavy metals may affect human health and environment stability. Conventional treatments for heavy metals removal from the soils include surface capping, soil flushing, air sparging, electrokinetic extraction, or vitrification, while chemical precipitation, coagulation, flocculation,

and membrane filtration may be used to clean up contaminated water (Vareda et al., 2019). However, the use of plants to remove or stabilize pollutants has also been proposed as a promising alternative to those expensive remediation methods, but requires the availability of heavy metal-resistant species (Ali et al., 2013; Jaskulak et al., 2020).

Toxic effects of heavy metals on plants include alteration of mineral nutrition, photosynthesis modification in relation to reduced chlorophyll and carotenoid content, induction of oxidative stress or alteration of the plant water and hormonal status resulting in growth reduction and thus biomass production (Chandra and Kang 2016; Berni et al.,

Abbreviations: AAT, aspartate aminotransferase; AKR, probable aldo-keto reductase; BG, glucan endo-1_3-beta-glucosidase; CAD1, cinnamyl alcohol dehydrogenase 1-like; CAT, catalase; CBM3a, his-tagged recombinant protein recognizing crystalline cellulose; CES, cellulose synthase; CH5, class V chitinase-like; COMT, caffeic acid 3-O-methyltransferase; CW, cell wall; FLA, fasciclin-like arabinogalactan protein; GABA, γ-aminobutyrate; GAE6, UDP-glucuronate 4-epimerase 6; GDPDL3-like, glycerophosphodiester phosphodiesterase; GluDC, glutamate decarboxylase; GluDH, glutamate dehydrogenase; GSH, glutathione; LAC4, laccase 4; LM10, monoclonal antibody recognizing xylan; MET1, methyltransferase; MTHFR, methylenetetrahydrofolate reductase; NiR, nitrite reductase; P5CS, Δ-1-pyrroline5-carboxylate synthase-like; PAE, pectin acetylesterase 3-like isoform X2; PC, phytochelatin; PCW, primary cell wall; PDF1, protodermal factor; PF, primary bast fibres; PME, pectinemethylesterase; PRX, peroxidase; RG-I, rhamnogalacturonan-I; RuBisCO, ribulose-1,5-bisphosphate carboxylase/oxygnase; SAMS, S-adenosylmethionine synthetase; SCW, secondary cell wall; SF, secondary bast fibres; SIR, sulfite reductase; SKU5, monocopper oxidase-like protein SKU5; SP, snap point; SuSy, sucrose synthase; TCA, tricarboxylic acid; UXS, UDP-glucuronic acid decarboxylase 6-like.

2018; Luyckx et al., 2019). Besides former industrial and mining areas which are frequently polluted by very high concentrations of toxic elements, agricultural soils may also be impacted by moderate pollution as a result of atmospheric contamination from surrounding areas and use of low quality fertilisers or pesticides. Since food crops cannot be cultivated in those areas as they represent a major risk for human health, non-food alternatives need to be proposed to producers (Pogrzeba et al., 2019; Feng et al., 2020).

Cannabis sativa L. is an annual high yielding industrial crop grown for its fibres and seeds (Morin-Crini et al., 2019; Pejic et al., 2009). As a multipurpose crop, C. sativa is receiving an increasing attention for the production of a wide range of bioactive molecules, but also as a source of feed in relation to the presence of oil, flour and protein and as a bioenergy crop (Andre et al., 2016; García-Tejero et al., 2019). Hemp can be used as potential crop for cleaning the soil from heavy metals (Citterio et al., 2003; Candilo et al., 2004; Angelova et al., 2004; Meers et al., 2005; Kumar et al., 2017) but could also be recommended as a good candidate for plant production on low contaminated substrates (Arru et al., 2004; Pietrini et al., 2019; Hussain et al., 2019a, 2019b). This implies that the non-edible parts of the plant need to be harvested and that hemp culture on marginal contaminated soil should focus on fibre cultivars (Linger et al., 2002), even if the seeds were recently reported to have a rather low metal content when plants were grown on slightly polluted substrates (Mihoc et al., 2012). Short hemp fibres, obtained as a waste from textile industry, can also be used as biosorbent for the removal of metal ions from polluted water (Vukcevic et al., 2014). of harvested fibres with maltodextrin-1,2,3, 4-butanetetracarboxylic polymer was reported ion-exchange properties improving heavy metal retention by a hemp-based felt (Loiacono et al., 2017). Besides such post-harvest treatments, heavy metals are also suspected to influence the pre-harvest development of hemp fibres, but data regarding the precise impact of element such as Cd and Zn on genes involved in this development in planta remain scant.

The stem of Cannabis sativa L. differentiate two types of fibres: (i) primary and secondary bast fibres associated with the conductive elements of phloem and bundles held together by pectins and lignin, and (ii) woody core fibres, called hurds or shivs, located in the xylem (Angelova et al., 2004; Behr, 2018; Guerriero et al., 2013; Morin-Crini et al., 2019). The hemp stem contains approximately 20-40 % of bast fibres and 60-80 % of hurds (Stevulova et al., 2014). The bast fibres initially elongate through intrusive growth, then cease elongation and start to thicken by secondary cell wall (SCW) deposition (Behr, 2018; Guerriero et al., 2017a). Plant fibre primary cell wall (PCW) consists mainly of cellulose, hemicelluloses and pectin (Pejic et al., 2009). They have the ability to bind heavy metal compounds (Vukcevic et al., 2014): metal ions indeed adsorb mainly to carboxylic (primarily present in hemicelluloses and pectin) and to some extent to hydroxylic (cellulose, hemicelluloses, and pectin) groups (Pejic et al., 2009; Hu et al., 2010; Vukcevic et al., 2014).

Secondary xylem, primary and secondary bast fibres undergo SCW deposition after the beginning of secondary growth (Behr, 2018). The composition of SCW is not similar for xylem- and phloem-located fibres. Xylem fibres differentiate a xylan-type SCW, while in the phloem fibres, SCW is of gelatinous (G-layer) type (Gorshkova et al., 2012). The CW of xylan-type fibres are lignified, contain predominantly xylan as hemicellulose constituent and show a typical layered structure (S1-S3) because of the different orientation of the cellulose microfibrils (Neutelings, 2011). The SCW of gelatinous fibres is also deposited in three layers, S1 and S2 compositions being similar to xylan-type wall while the G-layer has a very different organization: the major part of the G-layer is characterized by a high abundance of crystalline cellulose embedded in a rhamnogalacturonan-I (RG-I) matrix and a low content of xylan and lignin (Behr, 2018; Chernova et al., 2018; Guerriero et al., 2013, 2017a). The transition from bast fibre elongation via intrusive growth to SCW deposition occurs at a specific area called the "snap point" (SP)

(Gorshkova et al., 2003). The formation of SCW in hemp phloem fibres begins with the deposition of the Gn-layer ("gelatinous-new") (Chernova et al., 2018). During further CW development, the Gn-layer is transformed to a "solid" G-layer: enzymatic digestion of the pectic matrix leads to the compaction of cellulose microfibrils and final organization of the G-layer (Chernova et al., 2018). It was also recently reported that in the young hemp hypocotyl, the G-layer has a loose structure (Gf) and that it gets compacted at later stages of development (Behr et al., 2019).

Guerriero et al. (2017a, b) and Behr et al. (2018) have highlighted key genes coding for proteins involved in hemp fibre development, from bast fibre early growth stage (protodermal factor, PDF1), to SCW deposition (cellulose synthases *CESA4*, *CESA7*, *CESA8*), fasciclin-like arabinogalactan protein (*FLAs*), class III persoxidases; methyltransferase (*MET1*), S-adenosylmethionine synthetase (*SAMS*), including genes controlling the transition from elongation to thickening (acid phosphatase, AT1G04040). These molecular players are good candidates to evaluate the impact of heavy metal toxicity on plant fibre development. Besides transcriptomics, a proteomic analysis may also provide a useful set of information, but most of those analysis performed on *C. sativa* focused on cannabinoid synthesis rather than fibre CW formation (Aiello et al., 2016; Behr et al., 2018; Jenkins and Orsburn, 2020; Vincent et al., 2019). As far as exposure to heavy metal stress is concerned, data are only available for roots exposed to copper excess (Bona et al., 2007).

Any sustainable strategy helping the plant to cope with heavy metal toxicity could be usefully integrated in a phytomanagement scheme and this is especially the case for Si application (Wu et al., 2013; Adrees et al., 2015; Imtiaz et al., 2016; Etesami and Jeong, 2018; Bhat et al., 2019). Si is not considered essential for plant growth and development. However, increasing evidence in the literature show that this metalloid is beneficial to plants, especially under stress conditions (see Luyckx et al., 2017a for review). In hemp, the positive effects of Si on biomass production may be explained, among others, by an action on phytohormone balance regulating important stages of bast fibre development (Luyckx et al., 2017b). Si was recently shown to mitigate the impact of salt stress on hemp leaves (Berni et al., 2020). Guerriero et al. (2019) identified in hemp two NOD26-like intrinsic proteins exhibiting typical features reported to be associated with Si transport and revealed the presence of Si in isolated trichomes from the leaves, but also in the distal CW of bast fibres.

Silica hydrophobic coating is frequently used during processing of harvested fibres to reduce their water absorption (Jiang et al., 2018) or as a fire retardant (Branda et al., 2016). According to Hussain et al. (2019b), silica matrix used for composite with hemp shive may assume multifunctional purposes which suggest that Si may, to some extent, directly interact with hemp fibres. However, the impact of Si on hemp fibre during their development process remains poorly documented, especially in the case of heavy metal-exposed plants.

The present work was therefore undertaken in order to determine the impact of Cd and Zn in the presence or absence of Si on plant development and fibre differentiation in relation to heavy metal accumulation in young stem of *C. sativa*. The expression of genes regulating fibre development was analyzed and the proteome of hypocotyls was characterized.

2. Material and methods

2.1. Plant material and growing conditions

Seeds of a monoecious hemp fibre variety (*Cannabis sativa* cv. Santhica 27) were sown in loam substrate in greenhouse conditions. After one week, the obtained seedlings were transferred to nutrient Hoagland solution (in mM: $2.0~\text{KNO}_3$, $1.7~\text{Ca(NO}_3)_2$, $1.0~\text{KH}_2\text{PO}_4$, $0.5~\text{NH}_4\text{NO}_3$, $0.5~\text{MgSO}_4$, and in μM : $17.8~\text{Na}_2\text{SO}_4$, $11.3~\text{H}_3\text{BO}_3$, $1.6~\text{MnSO}_4$, $1~\text{ZnSO}_4$, $0.3~\text{CuSO}_4$, $0.03~\text{(NH}_4)_6\text{Mo}_7\text{O}_{24}$ and 14.5~Fe-EDDHA) in 25~L tanks. For each tank, 10~seedlings were adapted to plugged holes in a polystyrene plate floating at the top of the solution. Tanks (24) were

placed in a phytotron under fully controlled environmental conditions (permanent temperature of 24 \pm 1 $^{\circ}\text{C}$ with a mean light intensity of 230 $\mu\text{moles m}^{-2}\text{s}^{-1}$ provided by Phillips lamps (Philips Lighting S.A., Brussels, Belgium) (HPI-T 400 W), with a photoperiod of 16 h under a relative humidity of 65 %).

After one week, half of the tanks received Si in the form of H₂SiO₃ to a final concentration of 2 mM Si. Metasilicic acid was obtained from a pentahydrate sodium metasilicate (Na₂SiO₃ x 5 H₂O) which was passed through an H⁺ ion exchanger resin IR 20 Amberlite type according to Dufey et al. (2014). Tanks were randomly arranged in the phytotron and nutrient solution was permanently aerated by SuperFish Air Flow 4 pump. After an additional week of acclimatization, heavy metals were applied in the form of CdCl₂ (final concentration of 20 µM) and ZnCl₂ (100 µM) as previously stated (Luyckx et al., 2017b). The pH of the solution was maintained at 5.5. Solubility of added heavy metals was confirmed by the Visual MINTEQ09 software. Six treatments were thus defined, considering the presence of heavy metals and the concomitant presence or absence of Si and will be designed as C (control: no heavy metals and no Si), CSi, Cd, CdSi, Zn and ZnSi (4 tanks per treatment). Plants were harvested after one week of treatment and roots were thoroughly rinsed in deionized water: 4 plants per tank were selected to measure stem length and diameter, number of leaves, root length, fresh and dry weight (obtained after 72 h of incubation in an oven at 70 °C) and heavy metal concentration in roots, leaves and stems. The remaining plants from the same tank were pooled: roots, leaves and stems were separated. Hypocotyl parts of the stem were separated from epicotyls, frozen in liquid nitrogen and then stored at -80 °C until subsequent transcriptomic and proteomic analysis. Segments of stem in the internode containing the SP were rapidly excised for confocal microscope observation.

2.2. Mineral concentration

Plant samples were dried at 70 °C for 72 h. For Cd and Zn quantification, 50-100 mg dry material (DM) were then digested in 68~% HNO $_3$ and acid evaporated to dryness on a sand bath at 80~%C. Minerals were incubated with a mix of HCl 37 %-HNO $_3$ 68~% (3:1) and the mixture was slightly evaporated, dissolved in distilled water and filtrated on Whatman n°2 filter papers. For Si quantification, 1 g DM were placed in an oven and heated to 500~% for 48 h. Ashes were then mixed with 0.4~g tetraborate and 1.6~g metaborate and heated to 1000~% for 5 min. The obtained pellet was dissolved with 25~% HNO $_3$, Cations were quantified by Inductively Coupled Plasma-Optical Emission Spectroscopy (Varian, type MPX).

2.3. Gene expression analysis

Total RNA was extracted from hypocotyls according to Guerriero et al. (2017a) and Mangeot-Peter et al. (2016) using the RNeasy Plant Mini Kit (Qiagen) treated on-column with DNase I. The RNA concentration and quality were measured for each sample by using a Nanodrop ND-1000 (Thermo Scientific) and a 2100 Bioalyzer (Agilent Life Sciences), respectively. The RNA integrity number (RIN) of all samples was higher than 7, and the ratios A260/280 and A260/230 were between 1.7 and 2.4. The extracted RNA was retrotranscribed into cDNA using the SuperScript II reverse transcriptase (Invitrogen) and random primers, according to the manufacturer's instructions. The synthesized cDNA was diluted to 2 ng/μL and used for the RT-qPCR analysis in 384-well plates. An automated liquid handling robot (epMotion 5073, Eppendorf) was used to prepare the 384-well plates. To check the specificity of the amplified products, a melt curve analysis was performed. The relative gene expression was calculated with qBase PLUS (version 2.5, Biogazelle) by using the reference genes (eTIF4E, TIP41, F-box and RAN, Mangeot-Peter et al., 2016). Statistics (ANOVA2) were performed using R (version 3.3.1).

The target genes were chosen on the basis of preliminary results

(Guerriero et al., 2017a, 2017b) and belong to genes regulating the lignification process [methyltransferase (*MET1*), S-adenosylmethionine synthase (SAMS), class-III peroxidases (*PRX49, PRX 52, PRX 72*), genes coding for SCW cellulose synthases (*CesA4, CesA7, CesA8*) and fasciclin-like arabinogalactan protein (*FLA3, FLA11, FLA13, FLA19*).

The corresponding primers were designed using Primer3Plus (http://www.bioinformatics.nl/cgi-bin/primer3plus/primer3plus.cgi/) and verified with the OligoAnalyzer 3.1 tool (Integrated DNA technologies, http://eu.idtdna.com/calc/analyzer). Primer efficiencies were checked via qPCR using 6 serial dilutions of cDNA (10, 2, 0.4, 0.08, 0.016, 0.0032 ng/µL). For each considered gene, selected primers are listed in Table S1.

2.4. Proteomic analysis

For each sample, 500 mg fresh material (FM) of *C. sativa* hypocotyl were homogenized in a Potter (Wheaton) homogenizer in 2 mL of homogenization buffer (50 mM Tris, pH 7.5 (HCl), 2 mM EDTA, 5 mM dithiothreitol (DTT), protease inhibitor mix (1 mM phenylmethylsulfonyl fluoride (PMSF), 2 $\mu g/mL$ each of leupeptin, aprotinin, antipain, pepstatin, and chymostatin), 0.6 % w/v polyvinylpolypyrrolidone, 30 mM spermine) and the homogenate centrifuged for 5 min at 2000 rpm and 4 °C. Protein extracts were centrifuged at 2 °C for 30 min at 54,000 rpms (TLA55, Optima-Beckman-Coulter) to obtain a pellet of crude membranes and supernatant.

Twenty µg of each sample were transferred to 0.5 mL polypropylene Protein LoBind Eppendorf tubes and precipitated with chloroform-methanol method (Wessel and Flügge, 1984); 20 µL of 100 mM TEAB (triethylammonium bicarbonate) were then added to reach pH 8.5. Proteins were reduced by 5 mM DTT (dithiothreitol) and alkylated by 15 mM iodoacetamide. Proteolysis was performed with 0.5 µg of trypsin and allowed to continue overnight at 37 $^{\circ}$ C. Each sample was dried under vacuum with Savant Speed Vac Concentrator.

Before peptide separation, the samples were dissolved in 20 μL of 0.1 % (v/v) formic acid and 2 % (v/v) acetonitrile (ACN). Peptide mixture was separated by reverse phase chromatography on a NanoACQUITY UPLC MClass system (Waters) working with MassLynx V4.1 (Waters) software; 200 ng of digested proteins were injected on a trap C18, 100 Å $5\;\mu m,\,180\;mm\;x\;20\;mm$ column (Waters) and desalted using isocratic conditions with at a flow rate of 15 $\mu L/min$ using a 99 % formic acid and 1 % (v/v) ACN buffer for 3 min. The peptide mixture was subjected to reverse phase chromatography on a C18, 100 Å 1.8 mm, 75 μm x 150 mm column (Waters) PepMap for 120 min at 35 $^{\circ}$ C at a flow rate of 300 nL/min using a two part linear gradient from 1 % (v/v) ACN, 0.1 % formic acid to 35 % (v/v) ACN, 0.1 % formic acid and from 35 % (v/v) ACN, 0.1 % formic acid to 85 % (v/v) ACN, 0.1 % formic acid. The column was re-equilibrated at initial conditions after washing 10 min at 85 % (v/v) ACN, 0.1 % formic acid at a flow rate of 300 nL/min. For online LC-MS analysis, the nanoUPLC was coupled to the mass spectrometer through a nano-electrospray ionization (nanoESI) source emitter.

IMS-HDMSE (Ion Mobilty Separation-High Definition Enhanced) analysis was performed on an SYNAPT G2-Si high definition mass spectrometer (Waters) equipped with a NanoLockSpray dual electrospray ion source (Waters). Precut fused silica PicoTipR Emitters for nanoelectrospray, outer diameters: 360 μm ; inner diameter: 20 μm ; 10 μm tip; 2.5" length (Waters) were used for samples and Precut fused silica TicoTipR Emitters for nanoelectrospray, outer diameters: 360 μm ; inner diameter: 20 mm; 2.5" length (Waters) were used for the lock mass.solution. The eluent was sprayed at a spray voltage of 2.4 kV with a sampling cone voltage of 25 V and a source offset of 30 V. The source temperature was set to 80 °C. HDMSE method in resolution mode was used to collect data from 15 min after injection to 106 min. This method acquires MSE in positive and resolution mode over the m/z range from 50 to 2000 with a scan time of 1 s. with a collision energy ramp starting from ion mobility bin 20 (20 eV) to 110 (45 eV). The collision energy in

the transfer cell for low-energy MS mode was set to 4 eV. For the post-acquisition lock mass correction of the data in the MS method, the doubly charged monoisotopic ion of [Glu1]-fibrinopeptide B was used at 100 fmol/mL using the reference sprayer of the nanoESI source with a frequency of 30 s at 0.5 mL/min into the mass spectrometer.

HDMSE data were processed with Progenesis QI (Nonlinear DY-NAMICS, Waters) software using *C. sativa* NCBI database downloaded october 8, 2019. Carbamidomethylation as the fixed cysteine modification, oxidation as the variable methionine modification, trypsin as the digestion enzyme were selected and one miscleavage allowed.

2.5. Confocal microscope observation

Segments of stem tissue in the internode containing the SP were rapidly excised from fresh plants with a scalpel and dipped into tissue freezing media (O.C.T., Tissue Tek, Jung etc.), and into propane cooled by liquid nitrogen. The plant pieces were next sectioned at 60 μm thickness with a Leica CM3050 cryotome (Leica), placed in Al holders and transferred to an Alpha 2–4 Christ freeze dryer ($-50~^{\circ}\text{C},\,0.04~\text{mbar},\,3~\text{days}).$ Freeze-dried cross-sections were photographed using a digital camera (AxioCam) mounted on a Zeiss Axioscope 2 fluorescence microscope (wavelenght: 405 nm).

2.6. Immunohistochemistry

Hemp stems sections of 5 mm in the internode containing the SP were fixed in FAA (90 mL ethanol 70 %/5 mL glacial acetic acid/5 mL formaldehyde 35 %) for 24 h at room temperature, dehydrated in ethanol series (70 %–80 %-100 %) and ethanol:butanol series (2/3:1/3–1/3:2/3 – butanol 100 %), impregnated in paraffin 12 h at 37 °C and 24 h at 60 °C, and finally included. The plant pieces were next sectioned at 10 μ m thickness with a microtome (Leica), and used for immunohistochemistry (IHC). Image acquisition was performed with a confocal microscope LSM 710 (Zeiss).

The protocol used for immunohistochemistry is described by Behr et al. (2016): LM10 (xylan, Plant Probes) antibody was diluted 10-fold in milk protein (MP)/PBS (5 % w/v). Sections were then incubated for 1.5 h, rinsed three times in PBS and incubated for 1.5 h with the anti-rat IgG coupled to FITC (Sigma) diluted 100-fold in MP/PBS. Before observation, three washings with PBS were performed. CBM3a (crystalline cellulose, Plant Probes) was diluted to 10 µg/mL in MP/PBS, incubated in mouse anti-His monoclonal antibody (1 % in MP/PBS, Sigma) and finally incubated in 50-fold diluted anti-mouse IgG coupled to FITC (Sigma). Each incubation lasted for 1.5 h. Between each step, three washes with PBS were performed. The slides were observed with the following settings: excitation at 488 nm, filter HFT 493/564 and emission recorded with LP 505. The microscope settings were kept rigorously constant between the different observations for a given epitope. Negative controls where either the primary or secondary antibody was omitted resulted in a very weak and negligible signal.

Images were imported into ImageJ to get quantitative data and were calibrated with the "Set Scale" command. Fluorescence intensity in the different stem tissues was measured using the "Freehand selections" command the, and the "Straight line" was used to measure both the diameter and the CW thickness of bast fibres (primary and secondary bast fibres). Three plants per treatment were analyzed and 6–10 measurements were made for each one.

2.7. Statistical analysis

Four independent biological replicates and three technical replicates were analyzed for each condition. Normality of the data was verified using Shapiro-Wilk tests and the data were transformed when required. Homogeneity of the data was verified using Levene's tests. ANOVA 2 were performed at a significant level of p-value <0.05 using R (version 3.3.1) considering the type of heavy metal treatment, and the Si

application as main factors. Means were compared using Tukey's HSD all-pairwise comparisons at $5\,\%$ level as a post-hoc test.

For proteomic analysis, non-conflicting method was used as relative quantification method. To identify statistically significant differentially expressed proteins, combined criteria of a minimum of three or greater unique peptides, a two-fold change ratio or greater and a p-value <0.05 in the Student's t-tests were adopted.

3. Results

3.1. Impact of Cd and Zn on plant physiological parameters

Phenotypes of plant cultivated in the different conditions are illustrated in Fig. S1. In the absence of heavy metals, Si had no impact on root and stem length, stem diameter and total leaf number (Table 1). In contrast, both Cd and Zn in the absence of $\rm H_2SiO_3$ significantly reduced root length, stem diameter and total leaf number while only Cd had a significant impact on stem length. The application of 2 mM $\rm H_2SiO_3$ tended to slightly mitigate the deleterious impact of heavy metal stress on root length and stem diameter, although no significant difference was recorded for the mean values. Heavy metals also significantly reduced root, stem and leaf dry weight (DW) (Table 2), Cd being more toxic than Zn for root and leaves. Heavy metals reduced the water content in stems, only. Si tended to slightly increase the mean DW of roots in Cd-treated plants and of both stem and leaves in Zn-treated ones, although the difference was not significant considering the high variability occurring among replicates.

3.2. Mineral content

Cd (Table 3) was detected in Cd- and CdSi-treated plants only (detection limit: 0.013 mg/L). The root Cd concentration was significantly higher than in leaves (p-values <0.01) while the stem showed an intermediate value. $\rm H_2SiO_3$ application slightly decreased Cd content in roots and stems. Zn excess strongly increased root, stem and leaf Zn concentration (Table 3), with higher values in roots than in stems and leaves (p-value <0.01). Exposure to $\rm H_2SiO_3$ increased root and leaf Si concentration in the absence and in the presence of heavy metals but the recorded increase in Si was not significant in the stem (Table 3). Si concentration was higher in the roots and leaves of ZnSi treated plants than in those of CdSi-treated ones while an opposite trend was recorded for the stem.

3.3. Gene expression in the stem

The hierarchical clustering of the expression profiles (represented as a heatmap; Fig. 1) for the various treatments was performed using a Euclidean distance matrix in complete linkage. The clustering resulted in a separation between control plants (C, CSi), Cd exposed plants (Cd,

Table 1 Root length, stem length and diameter, and total leaf number of *Cannabis sativa* (cv. Santhica 27) exposed for one week to Cd (20 μ M) or Zn (100 μ M), in the presence or in the absence of 2 mM H₂SiO₃. Data are means \pm standard errors (n=4). Values with different letters are significantly different (P<0.05; Tukey's HSD all-pairwise comparisons).

Treatment	Root length (cm)	Stem length (cm)	Stem diameter (mm)	Total leaf number
С	$42.60 \pm 2.21 \ b$	$27.12 \pm 5.91 \ b$	$7.13 \pm 0.77~c$	$10.20 \pm 0.45 \ b$
CSi	$40.92 \pm 8.49 \ b$	$29.78 \pm 7.49~b$	$6.68\pm0.50~bc$	$10.20\pm0.45~b$
Cd	$31.22\pm3.99~a$	$12.66\pm2.64~a$	$4.58\pm0.48~a$	$7.80\pm0.84~a$

CdSi) and Zn exposed plants (Zn, ZnSi). In plants that were not exposed to heavy metals, exposure to Si stimulated the expression of CesA4, CesA8, FLA11, and MET1, the difference being significant for CesA4, only.

In Cd-stressed plants, several transcripts related to SCW formation were less abundant as compared to the control, notably CesA7, CesA8, FLA3, FLA11, FLA13, and FLA19 involved in cellulose deposition (Behr et al., 2016; Guerriero et al., 2017b). In the same plant samples, somes genes controlling several biochemical pathways, including the regulation of lignification, displayed a different expression pattern: MET1 and SAMS (generation of methyl donors) were down-regulated by Cd, whereas PRX49, PRX52 and PRX72 (genes controlling lignification; Herrero et al. (2013) and previously shown to be upregulated in hypocotyls aged 15 and 20 days; Behr (2018) were more expressed in Cd-treated plants than in controls. No significant effect of Si application on the expression of genes in Cd-stressed plants was detected but, once again, trends may be observed: PDF1, a gene shown to be upregulated in the young hemp internode (Guerriero et al., 2017a) and maybe involved in fibre initation, CesA4, FLA13, FLA19, FLA3, MET1, PRX49, PRX52 seem to be more expressed in CdSi-treated plants than in Cd exposed ones, while a gene encoding an acid phosphatase influencing CW-related processes in bast fibres during the transition from elongation to thickening (Guerriero et al., 2017a), SAMS and PRX72 showed an inverse trend.

In Zn-treated plants, *CesA4*, *FLA19*, *PRX49*, *PRX52* and the gene coding for the acid phosphatase were upregulated compared to control plants. A higher expression of *PDF1*, *CesA8* and *CesA7* was observed in Zn-treated plants when exposed to Si comparatively to Zn-treated plants cultivated in the absence of Si. The abundance of transcripts coding for the acid phosphatase, PDF1, FLA19, CESA7 and PRX49 were higher in ZnSi-treated plants than in those exposed to Si in the absence of heavy metals (CSi).

3.4. Proteomics

The data relative to the impact of the treatments on protein

regulation are provided in Table 4 which simultaneously considers soluble and membrane-bound protein fractions.

Hemp response to Cd resulted in a significant increase in the abundance of 2 proteins involved in tricarboxylic acid (TCA) pathway, one controlling callose remodelling (glucan endo-1_3-beta-glucosidase, BG), one protein regulating lignin biosynthesis (cytochrome P450 CYP73A100-like, CYP73A100), a protein regulating proline biosynthesis (Δ -1-pyrroline-5-carboxylate synthase-like, P5CS), a protein responsible for glutamate metabolism (glutamate dehydrogenase, GluDH), a protein involved in sulphate assimilation (sulfite reductase, SIR), 3 protein involved in protein synthesis and 3 involved in proteolysis, 3 proteins controlling transport, 4 involved in ionic homeostasis, a protein managing cell organization, 4 proteins involved in signal transduction and metabolism regulation and 5 in cell rescue. Conversely, Cd treatment negatively impacted the abundance of a protein involved in photosynthesis (ribulose-1,5-bisphosphate carboxylase/oxygnase, RuBisCO small subunit), 2 proteins regulating carbohydrate metabolism, one in TCA cycle, one protein involved in fermentation, a protein controlling γ-aminobutyrate (GABA) shunt, proteins controlling cellulose biosynthesis (sucrose synthase, SuSy; cellulose synthase; CESA7, CESA8), lignin biosynthesis (caffeic acid 3-O-methyltransferase, COMT; laccase 4, LAC4; CYP736A12), lignin monomer methylation (methylenetetrahydrofolate reductase, MTHFR) and pectin synthesis (UDP-glucuronate 4-epimerase 6, GAE6), 2 proteins involved in amino acid metabolism, 6 proteins regulating protein synthesis and one involved in protein folding, 2 proteins involved in transport, 4 proteins managing cellular organization, 6 proteins involved in signal transduction and metabolism regulation and a protein controlling cell rescue (class V chitinase-like, CH5) (Table 4). Cd had no direct impact on proteins regulating cell division but it nevertheless affected the cytoskeleton through a decrease in tubulin alpha-1 chain. As shown in Fig. 2, the most important category of proteins up-regulated by Cd was related to cell rescue and defence and includes protein dealing with oxidative stress such as catalase and peroxidases. Conversely, most down-regulated proteins were related to SCW synthesis, as it was the case for cellulose synthase CESA7 and CESA8 or for caffeic acid 3-O-methltransferase

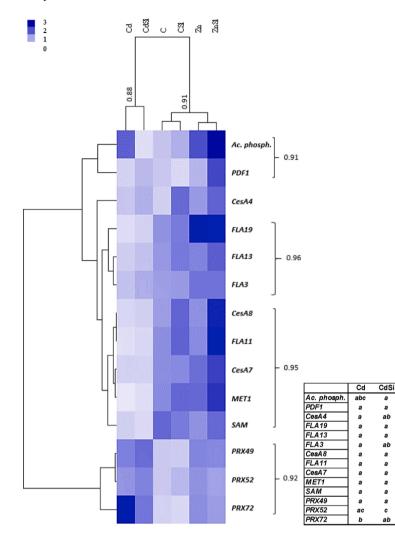

Fig. 1. Heatmap hierarchical clustering showing the expression of genes assessed by RT-qPCR in hypocotyls of hemp plants. Plants were exposed for one week to Cd (20 μM) or Zn (100 μM) in the presence or absence of Si (2 mM) (C: control plants not exposed to heavy metals). Values represent Normalized Relative Quantities (NRQs). For each group, the Pearson coefficient is provided. The table represents statistical analyses of the heatmap hierarchical clustering. The different letters indicate that the values are significantly different from each other (P < 0.05; Tukey's HSD all-pairwise comparisons).

which catalyses the multi-step methylation reactions of hydroxylated monomeric lignin precursor.

Among proteins up-regulated by Zn exposure (Table 4; Fig. 2), 4 are involved in carbohydrate metabolism, one in callose remodelling (BG), one in CW expansion (monocopper oxidase-like protein SKU5), one in cellulose biosynthesis (SuSy), one in xylan biosynthesis (UDP-glucuronic acid decarboxylase 6-like, UXS), on in SCW synthesis (fasciclin-like arabinogalactan protein 12, FLA12), 2 in lignin biosynthesis (cinnamyl alcohol dehydrogenase 1-like, CAD1; and CYP73A100), one in pectin acetylation (pectin acetylesterase 3-like isoform X2, PAE), one in proline biosynthesis (P5CS), 2 in nitrate and sulphur assimilation (NiR, SIR), one in pyrimidine metabolism, 4 in protein synthesis and 1 in protein folding, 5 in proteolysis, 5 are involved in transport, 3 in ionic homeostasis, one in cell division, 7 in signal transduction and metabolism regulation, and 7 assume key functions in cell rescue. Zn exposure also reduced the abundances of a protein involved in photosynthesis (RuBisCO small subunit), a protein controlling in SCW synthesis (FLA12), a protein controlling the accumulation of crystalline cellulose (glycerophosphodiester phosphodiesterase GDPDL3-like), 2 involved in lignin biosynthesis (LAC4 and CYP736A12), one is involved in amino acid synthesis (aspartate aminotransferase, AAT), one regulating transcription, 16 involved in protein synthesis and folding, one managing in proteolysis, 5 controlling transport, 2 in ionic homeostasis, one in cell organization (actin), 5 playing role in signal transduction and metabolism regulation and 2 involved in cell rescue (catalase, CAT; probable aldo-keto reductase, AKR). The most important category of proteins down-regulated by Zn toxicity were involved in protein processing. It has to be noticed that only a minor proportion of proteins (40) were affected by both Cd and Zn, suggesting that the two heavy metals have a quite different impact on protein regulation in C. sativa, despite the fact that they share numerous chemical properties (Jaskulak et al., 2020). When a same protein was affected by both heavy metals, Cd and Zn had similar impacts in terms of up- or down-regulation and no opposite effect was recorded. This was especially the case for LAC4 whose abundance was reduced by both heavy metals, and for glucan endo-1, 3- β -glucosidase (BG) involved in callose degradation which was increased by Cd and by Zn.

bc

The number of proteins affected by Si exposure was by far lower than the number of proteins affected by heavy metals (Table 4 and Fig. 2). Exposure of hemp plants to Si in the absence of heavy metal stress upregulated proteins involved in photosynthesis (1), amino acid metabolism (MS1), protein synthesis (3), transport (2) and cell rescue (especially MDHAR involved in Asada-Halliwell cycle). Si significantly decreased the accumulation of some proteins involved in photosynthesis (1), SCW formation (FLA12), protein synthesis (4), cell organization (1), signal transduction and metabolism regulation (3) and cell rescue (2). Si had contrasting impact on proteins involved in lignin biosynthesis since it increased the abundance of caffeic acid 3-O-methyltransferase (COMT), while it decreased the abundance of a laccase (LAC4).

Si had a specific impact on some proteins observed in CdSi treatment comparatively to plants exposed to Cd in the absence of Si: 55 % of those proteins (10 among 18) were specifically regulated by this treatment and remained unaffected by Cd or Si applied alone. This was the case for $\beta\text{-}D\text{-}xylosidase$ and dehydrorahmnose reductase. Additional Si to Cd-

Table 4 List of proteins with significant quantitative changes of hemp stems in response to Cd, Zn and Si. Seedlings were exposed for one week either to Cd 20 μ M, Zn 100 μ M or Si 2 mM and proteins were extracted from hypocotyls. MFC: Max Fold Change. Proteins which abundance increased were indicated in green while those which abundance decreased are indicated in brown.

Table 4 (continued)

treated plants had no impact on other CW-related proteins previously mentioned to be affected by Cd treatment. Only 6 proteins were significantly regulated in ZnSi-exposed plants comparatively to Zn-treated ones and none of them were specifically regulated by Si in the absence of Zn. Similarly, one glucan endo 1,3- β -glucosidase and cellulose synthase A were respectively down- and up-regulated in response to ZnSi while these proteins were not affected by Si or by Zn applied separately.

3.5. Confocal microscopy and immunohistochemistry

Confocal microscope observation of stem sections (Fig. 3) revealed that Cd-treated plants displayed a lower level of lignin than controls and Zn-treated plants diplayed the highest proportion of lignin comparatively to control (C) or Cd-treated plants.

Confocal microscope observations were also carried out on 3 plants per treatment for immunochemistry. A monoclonal antibody recognizing xylan (LM10) and His-tagged recombinant protein recognizing crystalline cellulose (CBM3a) were used to study the impact of heavy metals on bast fibre development.

Figs. 4 and 5 allowed us to observe the histological modifications induced by heavy metals in the stem, as well as the impact of Si. In all plant sections, secondary growth can be observed by the presence of cambial cells and the typical radial organization of secondary xylem vessels. This radial organization was less marked for plants of Cd treatment without Si supply. Primary and secondary bast fibres were easily distinguishable in the stems of all treatments, except in stems of Cd-treated plants. The diameter of primary and secondary bast fibres was measured for each treatment. In plants of Cd treatment, the differentiation stage of secondary bast fibres was not compatible with an analysis. The diameter decreased in both types of bast fibres when plants were exposed to heavy metals (Cd and Zn, Fig. 6). Interestingly, the diameter increased in Cd-stressed plants when they were simultaneously exposed to Si, but this was not observed for Zn-treated plants. Both diameter and thickness of xylem vessels (Fig. 7) were smaller in plants exposed to Cd or Zn, with a contrasting effect of Si on the diameter of Cd and Zn treatments since it increased in Cd-stressed plants and decreased in plants treated with Zn.

On sections observed at the confocal microscope (Fig. 4), the xylan epitope was detected mainly in xylem cells (x) and in the C of primary

bast fibres (pf). In Cd, CdSi and Zn-treated plants a clear signal was also detected in collenchyma cells (c) (Table 5). The walls of primary bast fibres were more strongly labelled by this antibody in Cd-treated plants as compared to control ones. Si decreased the signal intensity in the collenchyma of Zn-treated plants. Using the ImageJ program, we measured the thickness of the signal distribution in bast fibres. The results presented in Table 5 show that in plants exposed to Cd or Zn, the thickness significantly decreased as compared to control plants. The same observation can be made when control plants are treated with Si (Table 5).

Crystalline cellulose was visualized with CBM3a. It was observed in all tissues, especially in collenchyma, xylem cells and in both primary and secondary bast fibres (Fig. 5). In the case of Cd-treated plants, the signal from secondary bast fibres was not detected but we saw an effect of Si in the case of Cd-treated plants: the differentiation stage of secondary bast fibres was sufficient to detect a signal. (Fig. 5). In Cd and Zn-treated plants, primary bast fibres displayed a more intense signal than the one detected in control plants. On the contrary, the signal was less intense in secondary fibres for the same plants (Fig. 5, Table 6). The thickness of the fibres as detected with the CBM3a signal, was influenced by the heavy metal treatment: it decreased in primary bast fibres of Cd-exposed plants and in secondary fibres of Zn-treated plants (Table 6).

4. Discussion

Cd and Zn are well known environmental pollutants which negatively affect plant growth and biomass production. Si has frequently been reported to protect plants from heavy metal toxicity (Adrees et al., 2015; Neumann and zur Nieden, 2001; Wu et al., 2013; Imtiaz et al., 2016). The present work confirms the deleterious impact of Cd and Zn on root and shoot growth in hemp and also highlights that both elements reduced the diameter of primary bast fibres, suggesting that these pollutants may have a negative impact on fibre yield in *C. sativa*. Although exogenous Si tended to improve the behaviour of plants exposed to heavy metals, such a positive impact remained unsignificant which could be partly explained by the high level of intraspecific variability still present in most hemp cultivars (García-Tejero et al., 2019; Mihoc et al., 2012; Jenkins and Orsburn, 2020), but also by the short duration of the simultaneous exposure to Si and heavy metals: it might indeed be argued that one week was not sufficient to detect the significant

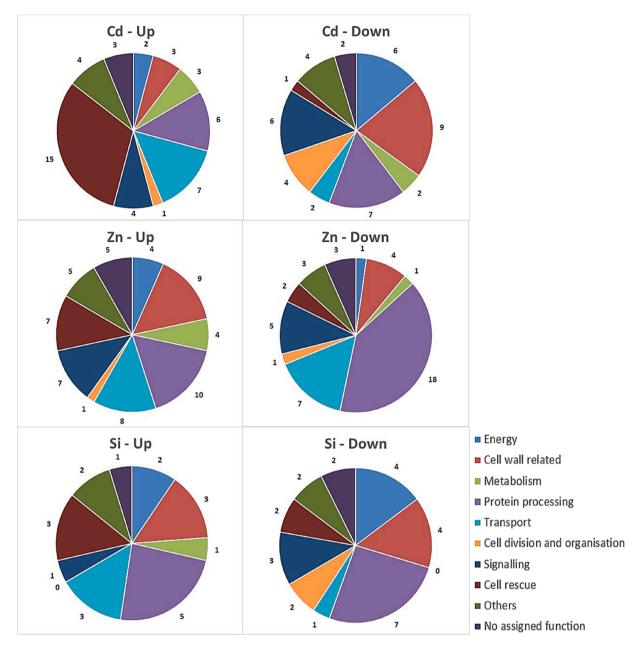

Fig. 2. Functional classification of proteins with significant quantitative changes in abundance in hemp hypocotyls in response to Cd, Zn and Si. Seedlings were exposed for one week either to Cd 20 μ M, Zn 100 μ M or Si 2 mM and proteins were extracted from hypocotyls. Mixed treatment (CSi, CdSi, ZnSi) are not indicated for the sake of clarity.

advantage conferred by Si to the growth of Cd- and Zn-treated plants, even if it allowed us to detect the impact of Si on some gene expression and specific protein abundances (see below).

A high concentration of Cd was recorded in roots and shoots of *C. sativa* after one week of treatment, reflecting the capacity of hemp to absorb and accumulate this toxic element. The recorded values were higher than those mentioned in the literature (Citterio et al., 2003; Angelova et al., 2004; Meers et al., 2005) which could be due to the fact that the present experiment was conducted in nutrient solution rather than in soils where Cd bioavailability constitutes a limiting factor for Cd absorbtion. Cd and Zn accumulations in stems and leaves of heavy-metal treated plants (expressed relative to the corresponding organ DW basis) were in the same order of magnitude, while Si accumulation in the stem of the Si-treated plants was clearly lower than in roots which are in close contact with the Si-containing nutrient solution, and in leaves which represent evaporative organs where accumulation of passively

translocated elements may occur. The low level of Si accumulation in stems, however, does not preclude a significant effect of Si on stem metabolism and mechanical properties. Indeed, Si is not uniformly distributed in plant tissues and accumulates at specific sites (Guerriero et al., 2020). As far as hemp stem is concerned, SIMS nano-analysis revealed the presence of Si in the distal CW of bast fibres (Guerriero et al., 2019).

Heavy metals also accumulate within the CW and this represents an efficient strategy preventing heavy metal accumulation in the cytosol. Vacuolar compartmentation of toxic elements is also considered as a valuable option for improving cell resistance (Sharma et al., 2016) and a positive effect of Cd on ABC transporters and oligopeptides transporters recorded in our study may be regarded as an attempt to limit Cd accumulation in the cytosol. Additional Si had a dual impact on these processes since it reduced the abundance of ABC transporters, but obviously increased the abundance of a protein involved in vesicular trafficking.

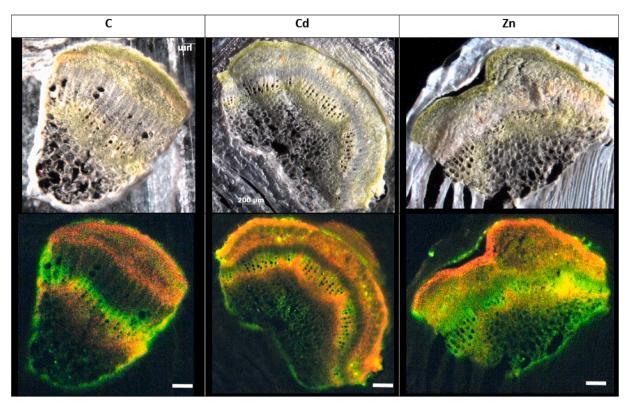

Fig. 3. Confocal microscope observation of hemp stem sections (60 μm) (Axioscope 2 MOT, 405 nm). Plants were exposed for one week to Cd (20 μM) or Zn (100 μM) (C: control plants not exposed to heavy metals). Fluorescence highlights lignified areas (yellow), areas containing chlorophyll (orange-red color), and simple phenols compounds (green). Scale bar: 200 μm.

Neumann and zur Nieden (2001) demonstrated in the Zn-resistant plant *Arabidopsis halleri* that Zn transiently accumulates as silicate in vacuolar vesicles and to a lower extent in the cytosol before being translocated to vacuoles where Zn-silicates are slowly degraded to SiO₂. This clearly suggests that Si distribution is not limited to the apoplasm.

Besides vacuolar sequestration, cell to cell trafficking constitutes a strategy to dilute heavy metals in the symplasm avoiding these ions to reach toxic levels. Callose (β -1,3-glucan) regulates plasmodesmatal permeability since an increase in plasmodesmata-localized callose is associated with a decrease in plasmodesmatal aperture (O'Lexy et al., 2018). In *A. thaliana*, O'Lexy et al. (2018) reported that Cd reduced plasmodesmatal permeability but our data on hemp stem provide a different picture since Cd and Zn increased the abundance of β -1, 3-glucosidase (BG) involved in callose breakdown. In contrast, Si reduced BG abundance in heavy-metal treated plants which may limit Cd and Zn mobility between cells. Silica precipitation may indeed be induced by callose which was shown to play a key role in silification of Si-accumulating species like *Equisetum arvense* and *Oryza sativa* (Guerriero et al., 2018a, 2018b, 2020).

After one week of treatment, heavy metals affected numerous proteins playing important roles in cell metabolism. Heavy metal toxicity is known to disturb photosynthesis and the fact that Cd and Zn decreased RuBisCO subunit was not unexpected. It is interesting to note, however, that in our study heavy metals mainly act on the chloroplastic small subunit confirming that this organelle is particularly sensitive to the deleterious effect of Cd and Zn (Lefèvre et al., 2014; Chandra and Kang, 2016). Cd also affected numerous enzymes involved in TCA cycle which could be related to an increase in the requirement of energy to cope with stress. In contrast, Zn excess did not directly impact TCA cycle but affected carbohydrate metabolism through an increase in DPE2 involved in maltose breakdown to glucose and by affecting the abundance of GALK which contributes to the synthesis of glucose-1-phosphate.

The non-protein amino-acid $\gamma\text{-aminobutyric}$ acid (GABA) is assuming

important functions in stress metabolism and signaling in plants and is synthesized via calcium/calmodulin-dependent glutamate decarboxylase activity (GluDC) (Seifikalhor et al., 2019). GluDC was strongly reduced in Cd-treated plants, but this should not be necessarily regarded as a symptom of injury and could be explained by the crucial role of glutamate as a precursor of other important molecules for stressed plants: glutamate is indeed converted to 2-oxoglutarate by glutamate dehydrogenase to fuel the TCA cycle and it is a precursor of proline which is a valuable protecting compound frequently overproduced in various stress conditions and which is suspected to directly chelate heavy metals (Lefèvre et al., 2014; Seifikalhor et al., 2019). The recorded increased abundance of P5CS (catalyzing the rate-limiting step of proline synthesis) in Cd- and in Zn-treated plants, supports the hypothesis that glutamate should remain available for the synthesis of this osmoprotectant. Glutamate is also an important precursor of the endogenous antoxidant glutathione (GSH) which is itself involved in the synthesis of phytochelatins (PC) directly implicated in heavy metal binding to cysteine, the complex being subsequently sequestered in vacuoles. Such a protecting process is especially efficient in response to Cd toxicity which triggers PC overproduction (Lefèvre et al., 2016).

A specific attention was paid to SCW deposition and a global overview of the impact of Cd and Zn on the synthesis of CW precursor is provided in Fig. 8. We studied gene expression and protein abundance in the hypocotyls of 28 days-old plants. At this stage, secondary xylem and secondary bast fibres, together with primary bast fibres, undergo SCW deposition (Behr, 2018). We analysed genes coding for bast fibre early growth stage (PDF1), genes involved in the transition from elongation to thickening (acid phosphatase, AT1G04040) and genes involved in SCW deposition (CesA4, CesA7 and CesA8, class III peroxidases, MET1 and SAMS).

Protodermal factor 1 (*PDF1*) is likely regulating hemp bast fibre early growth (Guerriero et al., 2017a). In 28-days hemp hypocotyls, fibres have completed their elongation and have started SCW deposition. Si

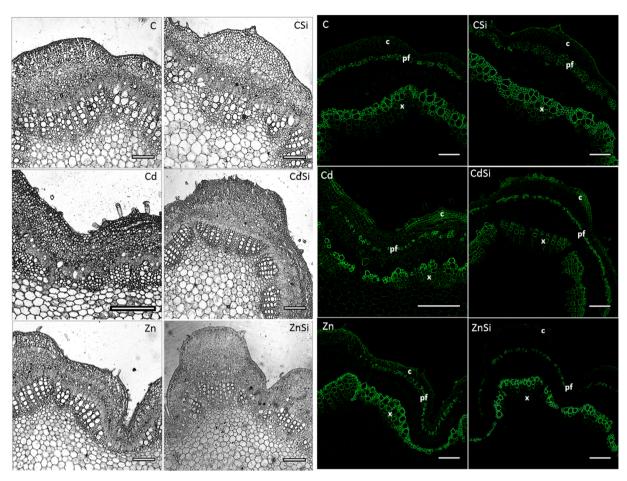

Fig. 4. Confocal microscope observation and immunodetection of the LM10 epitope specific for xylan in stem sections of *Cannabis sativa* (cv. Santhica 27). Plants were exposed for one week to Cd (20 μM) or Zn (100 μM) in the presence or in the absence of Si 2 mM. Control plants (C), Cd (Cd-treated plants), Zn (Zn-treated plants), with or without silicon (Si). Primary bast fibre (pf), secondary bast fibre (sf), xylem (x). Scale bar: 200 μm.

application induced an increased expression level of *PDF1* for plants exposed to Zn and to a lower extent to Cd (not significant) treatments. Similarly, acid phosphatase is controlling CW-related processes in bast fibres during the transition from elongation to thickening (Guerriero et al., 2017a) and appears to be more expressed in Cd- and Zn-stressed plants compared to control ones. These data suggest that the timing of fibre elongation and transition from elongation to thickening may be affected by heavy metals and that Si may have an influence on this process.

Cd and Zn had contrasting effects on genes and proteins involved in SCW deposition. While Cd negatively affected gene expression and protein abundance involved in CW deposition, Zn had an opposite impact although it did not act on the same target. Indeed, plants exposed to Cd showed a lower expression of two genes coding for the cellulose synthases CesA7 and CesA8, while in Zn-stressed plant CesA4 expression level increased. CesA4, CesA7 and CesA8 are usually associated with SCW biogenesis in both xylan-type and gelatinous-type SCW (Taylor et al., 2003; Gorshkova et al., 2012). They are therefore regulating the deposition of the SCW in both tissues (Behr, 2018). Our sample contained both bast fibres in the cortical part of the stem and xylem tissues in the core. It is therefore difficult to attribute the expression of these genes to xylan-type or gelatinous-type SCW. However, a recent study performed on flax has highlighted that both PCW- and SCW-related CesAs have a higher expression in phloem fibres depositing their G-layer (Mokshina et al., 2017). Our proteomic data corroborated transcriptomic results since Cd clearly decreased the abundance of CESA7 and CESA8 (Fig. 8).

To visualize Cd and Zn effect on cellulose deposition in stems, we

performed confocal microscope observations of His-tagged recombinant protein recognizing crystalline cellulose (CBM3a). In Cd and Zn treated plants, primary bast fibres displayed a signal that was more intense than the one detected in control plants, while abundance of CESA7 and CESA8 was shown to increase in Cd treated plants. Secondary bast fibres were not detected under Cd treatment. In Zn- and CdSi-treated plants. the signal was less intense than in control plants. It may therefore be hypothesized that heavy metals could modify bast fibres properties in relation to the decrease in cellulose abundance and to affect cellulose crystallinity detected by the recombinant protein used, although CBM3a is not fully specific to crystalline cellulose since it may also recognize xyloglucan present in PCW (Hernandez-Gomez et al., 2015). A Zn-induced decrease in GDPDL3 controling cellulose crystallisation (Fig. 8) as well as a decrease in the thickness of distribution of the CBM3a signal in primary (and secondary for CdSi-exposed plants) bast fibres of Cd-exposed plants and in secondary fibres of Zn-treated plants support this hypothesis. It could not be excluded, however, that cell wall modification possiby induced by heavy metals can also modify epitope accessibility, thus accounting for reduction of labelling. Cd (but not Zn!) also decreased the abundance of sucrose synthase (SuSy; Fig. 8) isoforms which provide UDP-glucose to cellulose synthase (Granot and Stein, 2019) and this may also contribute to alter cellulose synthesis in Cd-treated plants. The addition of Si to Cd-treated plants did not counteract the impact of Cd on gene expression or protein abundance, which clearly shows that Si may act on specific cues and must not be regarded as a Cd antagonist.

Fasciclin-like arabinogalactan proteins are cell surface proteins linked to CW deposition and stem development in many species, from

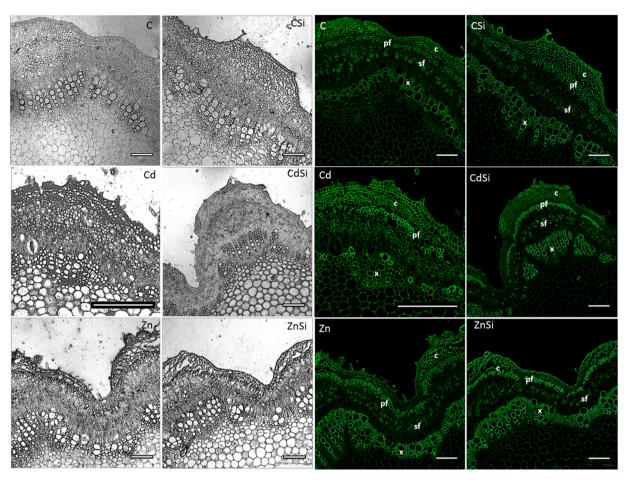

Fig. 5. Confocal microscope observation and immunodetection of the CBM3a epitope specific for crystalline cellulose in stem sections of *Cannabis sativa* (cv. Santhica 27). Plants were exposed for one week to Cd (20 μM) or Zn (100 μM) in the presence or in the absence of Si 2 mM. Control plants (C), Cd (cadmium treated plants), Zn (zinc treated plants), with or without silicon (Si). Primary bast fibre (pf), secondary bast fibre (sf), xylem (x). Scale bar: 200 μm.

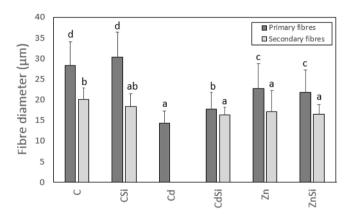

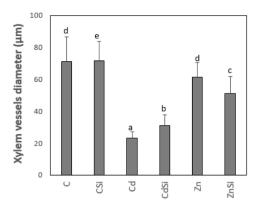

Fig. 6. Diameter of primary (FI) and secondary (FII) bast fibres in stems of *Cannabis sativa* (cv. Santhica 27). Plants were exposed for one week to Cd (20 μM) or Zn (100 μM) in the presence or in the absence of Si 2 mM. FII were not detected in Cd treated plants. The different letters indicate that the values are significantly different from each other (P < 0.05; Tukey's HSD all-pairwise comparisons). n=15 (3 plants/treatment, 5 fibres/plant).

herbaceous to woody (Behr, 2018). In hemp, Guerriero et al. (2017b) identified specific *FLAs* likely involved in SCW deposition during the thickening stage (*CsaFLA3-12-13-15-16-18-19*; Guerriero et al., 2017b). In our hemp hypocotyls, the number of transcripts of *FLA3*, *FLA13*, *FLA11* and *FLA19* was lower for Cd-stressed plants and *FLA19* expression was higher for Zn stressed plants compared to controls, confirming once

again a differential impact of the two considered heavy metals. *CsFLA13* and *CsFLA19* are highly expressed at the snap point as well as in older stem region (Guerriero et al., 2017b) and this might indicate a specific role in secondary growth. The concerted action of specific FLAs and chitinases may be involved in the transition from elongation to G-layer formation in hemp via the cleavage of the GlcNAc oligosaccharides part of FLA (Guerriero et al., 2017b): two endochitinase were increased in Cd-treated plants but their involvement in interaction with FLA is not demonstrated at this stage and requires further investigations

The present work demonstrates that Cd reduced the abundance of enzymes regulating lignin biosynthesis (decrease in COMT, CytP450, MTHFR, LAC4, CYP736A12; Fig. 8), while the situation was less clear for Zn which increased CAD1 but decreased LAC4 and CYP736A12. This contrasts with the results obtained in Medicago sativa where Cd exposure increased numerous proteins involved in the promotion of lignifiction (Gutsch et al., 2018). Hence, plant response may differ according to the species but also depending on stress duration: Gutsch et al. (2018) applied a long term Cd treatment while we recorded the data after one week only. Lignin is mainly present in shivs while bast fibres contain between 2-7 % lignin only (Guerriero et al., 2017a). Despite being a minor component in bast fibres, lignin is deposited in the S1-layer for mechanical reasons as the hypocotyl ages (Behr et al., 2019) and lignin in hemp bast fibres is rich in S-units as the hypocotyl ages, because of the high abundances of enzymes regulating monolignol methylation (Behr et al., 2018). It is well established that apoplastic H₂O₂ is important for lignification processes and it functions as a signaling molecule triggering enzymatic activities like those of CW-localized peroxidases (Cosio and Dunand, 2008; Gutsch et al., 2019a). A role of peroxidases in fibre

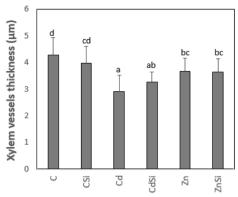

Fig. 7. Diameter and thickness of the xylem vessels cell walls in stems of *Cannabis sativa* (cv. Santhica 27). elongation and lignification through H_2O_2 production modulation has been recently reviewed (Berni et al., 2018): in cotton, Guo et al. (2016) observed that plants with downregulation of an ascorbate peroxidase (GhAPX1AT) are characterized by a significant increase in the number of fibres and by oxidative stress, which significantly reduces fibre elongation. During gene overexpression, cells show enhanced tolerance to oxidative stress suggesting that optimal levels of hydrogen peroxide are key mechanisms regulating fibre elongation (Guo et al., 2016). A high concentration of H_2O_2 would thus act as a signal for initiation of secondary wall thickening (Guo et al., 2016, Tang et al., 2014).

Peroxidases are necessary to initiate the polymerization of monolignols (Berthet et al., 2011; Chernova et al., 2018; Novo-Uzal et al., 2013). Our data show that in hemp stems, the expressions of PRX49 and PRX72, were higher under Cd/Zn treatment than in controls. Similarly, the abundance of PRX proteins increased (Fig. 8; PRX4 and PRX15 for Cd, PRX72 for Zn). Lignification occurs during normal growth but also

during defense responses: in hemp stems, the increased lignin-related transcripts could be a strategy to reduce HM entry into the cell by making the CW less permeable. Besides their role in lignification, PRXs may have a role in gelatinous CW modification. In experiments conducted by Behr et al. (2018), S lignin staining and peroxidase activity were overlapping in bast fibres, and they observed higher abundances of both transcripts (orthologs of AtPRX49, AtPRX52 and AtPRX72) and proteins (orthologs of AtPRX3, AtPRX52 and AtPRX54) at older stages of hemp development. Behr et al. (2019) also observed that in hemp, most of the signal of a peroxidase detected by the CsaPRX64 antibody had a distribution in the G-layer, with a scarcity or absence of signal in the S1-layer. The developing G-layer of phloem fibres from the tree *Mallotus* japonicus also shows a peroxidase activity, despite the absence of lignin (Nakagawa et al., 2014). The peroxidase activity detected in the G-layer may thus be involved in gelatinous CW modification, or in cellular defense mechanisms, and could be affected by plant exposure to Cd or Zn.

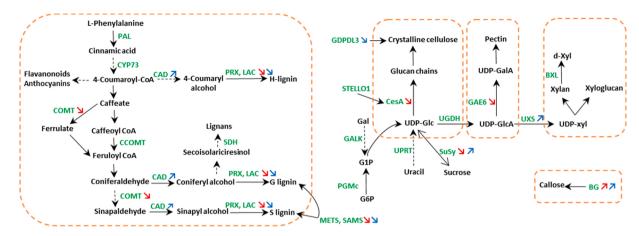

Fig. 8. Global overview of the impact of Cd and Zn on the abundance of proteins involved in the synthesis of cell wall precursors in hemp hypocotyls. Seedlings were exposed for one week either to Cd 20 μ M, Zn 100 μ M or Si 2 mM and proteins were extracted from hypocotyls. Colored arrows indicate a significant effect of Zn (in blue) or Cd (in red). The orange doted line delimits individual pathways.

Moreover, PRX72 participates in the biosynthesis of lignans, monolignol-derived molecules which may contribute to the hypolignification of bast fibres by subtracting monolignols from the lignin polymerization process (Behr, 2018). In lettuce and ryegrass, stem and root elongation is regulated by specific lignans, such as syringaresinol and sesamin (Yamauchi et al., 2015) and further experiments are thus required to precise the impact of Cd and Zn on lignan synthesis in hemp in relation to the observed root and shoot elongation decrease.

METS and SAMS are enzymes involved in the generation of methyl donors, required for G and S monolignol methylation (Behr et al., 2017; Shen et al., 2002; Tang et al., 2014). Their expression level decreased in the presence of Cd while a number of SAMS transcripts only slightly decreased in response to Zn excess. These genes are in general more expressed in the core tissue than in the cortical tissue (Guerriero et al., 2017b). Guerriero et al. (2017b) showed that the higher lignin content of the xylem tissues is correlated with an upregulation of the genes of the phenylpropanoid/monolignol pathway (CAD, METS, SAMS, PAL). We thus hypothesize that Cd-induced decrease in diameter and thickness of xylem vessels might be a consequence of METS and SAMS inhibition.

Xylan, the main hemicellulose of the SCW, was detected by LM10 antibody in xylem cells and the CW of primary bast fibres. In xylem cells, xylan is largely present in the lignifying SCW while in the bast fibres the G-layer is almost completely depleted in lignin and xylan (Behr, 2018). The chemical composition of xylan in these two tissues may be regulated to fulfil distinct functions, such as water conduction in xylem vessels and mechanical resistance in phloem fibres (Behr et al., 2019). The CW of primary bast fibres was more strongly labelled by the antibody in Cd-treated plants compared to control ones. In xylem vessels, only Zn exposure affected the signal intensity (higher). Considering that LM10 recognizes unsubstituted or low substituted xylan (McCartney et al., 2005), the results obtained suggest a decreased substitution of xylan in these CW, which may contribute to a higher CW stiffness caused by the HM (Shrestha et al., 2019). Chemical analyses will validate this hypothesis.

Pectin is considered as the main binding site for Cd. Structural changes frequently appear in the composition of pectic polysaccharide in plants exposed to Cd (Gutsch et al., 2019b). A variety of enzymes, including pectinesterase, β -like galactosidase, α -galactosidase are acting on the pectin network. This is especially the case for enhancement of pectin methylesterases (PME) which allow demethylesterification of homogalacturonan thus creating bing sites for Cd and avoiding its entry in cytosol (Hu et al., 2010; Gutsch et al., 2018). In Cd-treated plants, compared to control ones, the abundance of glucuronate 4-epimerase 6 (GAE6), involved in pectin synthesis, was decreased. We did not record any impact of heavy metals or Si treatment on PME abundance in our

hemp samples. It has however to be mentioned that Zn excess triggered pectin acetylesterase accumulation. Pectin acetylesterase (E.C. 3.1.1.6; PAE) cleaves the acetylester bond from pectin, especially in homogalacturonan where GalA residues can be acetylated at positions O-2 or O-3, also creating available binding sites for divalent cation binding.

It is concluded that Cd and Zn reduced bast fibre diameter in hemp and that Cd negatively affected lignin and cellulose synthesus while Zn had an opposite effect on cellulose. The two considered heavy metals had distinct effects on gene expression and specific protein synthesis. Silicon did not significantly improved plant growth on a short term basis but slightly decreased Cd content in roots and stems and had a specific impact on protein regulation in plants exposed to Cd stress.

Author's contributions

ML, GG and SL designed methodology; ML performed the whole experiment, treated and analyzed the data; AI contributed to mineral analysis and confocal microscopy; JFH and SL supervised the whole research process; ML and SL wrote the original draft; All authors reviewed the manuscript.

Declaration of Competing Interest

The authors report no declarations of interest.

Acknowledgements

This work was financed by ADEME (Agence de la Transition écologique; Convention MisChar n°1672C0044). The authors are grateful to Dr. C. Hachez and Mrs M.C. Eloy for assistance in using confocal microscope, to Dr P. Morsomme and Mr. H. Degand for their valuable help in proteomic analysis and to Mr. B. Capelle for his technical assistance during plant culture.
